Bactericidal in action Confidence in routine use

Prescribing information. Indications: Pipril is a broad spectrum bactericidal penicillin for the treatment and peri-operative prophylaxis of systemic or local infections caused by sensitive organisms. **Dosage:** Adult patients with normal renal function should receive 4-8g daily in divided doses for mild or uncomplicated infections. In serious or life-threatening infections 12-16g daily in divided doses. For peri-operative prophylaxis 2g just prior to surgery followed by at least two doses of 2g at four or six hour intervals. Patients with renal insufficiency may need dosage reduction – see Data Sheet. Children 2 months to 12 years of age: 100-300 mg/kg daily in three to four divided doses. Neonates and infants under two months of age: 100-300 mg/kg daily in two equally divided doses. **Contra-indications:** Penicillin or severe cephalosporin hypersensitivity. **Precautions:** Safety for use in pregnant or lactating women has not yet been established. **Side effects:** Uncommon and typical of injectable penicillins. **Administration:** Pipril is presented as 1g or 2g vials, 4g infusion bottles and 4g infusion packs containing piperacillin as piperacillin sodium. See Data Sheet or package leaflet for full details of preparation and administration. **Product Licence No.** 0095/0073 P.A. No. 37/53/7 **Basic NHS Price** 1g vial £3.07, 2g vial £6.08, 4g infusion bottle £12.01. 4g infusion pack (4g bottle, 50 ml WFI plus needle) £12.80.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**· 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give. (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s), title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality. Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

Br. J. Surg. 1989, Vol. 76, July, 659

Joint publication of papers in 'Surgery' and 'The British Journal of Surgery'

Readers may be surprised to find in this issue of *The British Journal of Surgery* a recent paper from the prestigious American journal *Surgery*, which is published in full in the format employed by *Surgery*. We have printed this paper as part of a joint experiment between *Surgery* and *The British Journal of Surgery*, to publish one paper from each other's journal for nine issues out of twelve in the next year, after which we will reassess the success of the venture. The Editorial Boards of *Surgery* and *The British Journal of Surgery* decided upon this policy to encourage the subscribers to both journals to investigate the contents of the other journal, and thereby promote both journals. The officers of *The British Journal of Surgery* feel that important work published in UK and European journals is inadequately reviewed by authors in the USA and they hope that this small step may have some effect in encouraging more personal subscriptions in the USA and wider reference to papers published from abroad. *The British Journal of Surgery* has expanded considerably over the last few years; it is now published in India, and the Spanish edition, published in Spanish and marketed in Spain and South America, appeared for the first time in January. We hope that this sample of the excellent material published in *Surgery* will interest our increased international readership.

The papers to be published in *The British Journal of Surgery* are selected by the Editors from selected manuscripts from *Surgery* and will be published in full, with no editorial alterations. Correspondence concerning these papers should be addressed to the Editor of the appropriate parent journal and the reference must be quoted as a paper from that journal. The 'Publishing Agreement' of both journals has been modified to insert a clause requesting permission from authors to allow this joint publication if their paper is selected; further consent from authors will not be sought after the paper has been accepted, provided they have agreed to this clause.

We would welcome correspondence concerning this venture.

Crawford Jamieson

The Chairman
The British Journal of Surgery

Ductal carcinoma in situ: a new clinical problem

Ductal carcinoma *in situ*, or as it is alternatively known intraduct carcinoma, is now accepted by pathologists as a preinvasive form of breast cancer. It is characterized by a proliferation of transformed and therefore malignant breast epithelial cells, entirely confined to the ducts and without invasion through the basement membrane into the stroma. Some lesions, although predominantly ductal carcinoma *in situ*, have a degree of 'microinvasion' and these tumours should be managed as invasive cancer. This article is concerned entirely with the management of the preinvasive tumours which, for two reasons, has recently developed as a significant clinical problem. Until the 1980s ductal carcinoma *in situ* was an uncommon pathological finding in women presenting with symptomatic breast lumps and was usually treated by mastectomy. This situation has been changed by the introduction of mammographic screening of asymptomatic women and the development and widespread acceptance of breast conserving treatment for cancer.

Breast screening centres such as that at Guildford, UK have seen a threefold to fourfold rise in the incidence of ductal carcinoma *in situ* which now makes up 12–15 per cent of screen-detected cancers[1]. Other units have reported ductal carcinoma *in situ* in as many as 44 per cent of their screen-detected cancers[2]. The introduction of breast screening in the UK will obviously result in a substantial increase in the number of intraduct carcinomas diagnosed, but there is a lack of information to guide the surgeon in their management. What little is known of the natural history of these lesions comes from retrospective reviews, and the results of treatment are almost all confined to anecdotal accounts based predominantly on patients presenting with palpable tumours and not the mammographically detected lesions that are becoming part of our clinical practice. Failure to treat screen-detected ductal carcinoma *in situ* adequately could possibly prejudice the effectiveness of breast screening programmes. It is of major concern that in implementing the Forrest Report little attention has been paid to the problems of treating preinvasive disease and an opportunity seems to have been lost to set up truly national studies and trials to resolve the unanswered questions.

The question that lies at the heart of these problems is that of the malignant potential of ductal carcinoma *in situ*. Evidence regarding the biological behaviour is limited as most cases in the past have been treated by mastectomy and we have to extrapolate from more indirect information. Two studies which reviewed a large number of benign breast biopsies, performed mainly for cystic disease, have identified cases of ductal carcinoma *in situ* previously misdiagnosed and treated only by excision biopsy[3,4]. Both studies found a similar incidence of invasive cancer (27–28 per cent) in the ipsilateral breast, usually in the same quadrant as the original biopsy. The mean time to detection of these invasive cancers ranged from 6·1 to 9·7 years. As these were retrospective studies some important details regarding follow-up and adequacy of excision were not available, but the studies indicate that a woman with ductal carcinoma *in situ* treated by excision alone has a substantial risk, around 11 times that of the general population, of developing an invasive cancer.

Post-mortem studies indicate that the incidence of ductal carcinoma *in situ* in normal breasts is low, around 5–6 per cent, but the disease may be present in up to 40 per cent of mastectomy specimens in association with invasive cancer. In studies where bilateral mastectomy has been undertaken for unilateral breast cancer, ductal carcinoma *in situ* has been found in the contralateral asymptomatic breast, in as many as 60 per cent of cases in one study[5]. Such figures are far greater than the reported incidence of multiple cancers in the same breast (0·1 per cent) and of bilateral breast cancer (4–10 per cent)[6]. These observations support the conclusion from the retrospective review of benign biopsies that not all ductal carcinoma *in situ* (especially the clinically silent cases) progress to the invasive form. However, the question of identification of which lesions remain static or become invasive remains unanswered.

Intraduct carcinomas can be categorized histologically into comedo, cribriform, papillary, solid and micropapillary types. Comedo and papillary forms are the most common and both are associated with multicentric disease; comedo is most likely to contain microinvasive elements[7] and is therefore the most biologically aggressive. Our group[8] has recently observed that the cellular DNA content of ductal carcinoma *in situ* is associated with prognosis. Aneuploid tumours more commonly had foci

0007-1323/89/070660-03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

of microinvasion and all patients who had local recurrence had aneuploid primary cancers. Less clear is the expression of the new proto-oncogene (C-erbB.2) which in invasive disease is amplified in approximately 15 per cent of tumours; these patients have been observed to have a poor clinical outcome. In a study of 45 clinical *in situ* tumours 19 (42 per cent) were found to over-express *neu*, and all of these were of the comedo type[9]. Further evidence for the more aggressive biological behaviour of comedo ductal carcinoma *in situ* comes from thymidine labelling studies which reported a significantly higher cellular proliferation rate in this type compared with other forms of intraduct cancer[10].

The clinical dilemma is apparent. How should a lesion of such uncertain natural history be treated? Theoretically, mastectomy will cure ductal carcinoma *in situ* and this is confirmed by a review of the literature. Of 323 cases of intraduct cancer treated by mastectomy and followed for a minimum of 5 years, there was a 1 per cent local recurrence rate and an overall survival rate of 98 per cent. With the adoption of conservation therapy, what should our approach be to a non-malignant tumour in which there is retrospective evidence of a 30 per cent recurrence rate when it is treated by excision alone[3,4]? Two prospective studies of excision alone, one for mammographically detected tumours and the other for palpable ductal carcinoma *in situ*, gave local recurrence rates of 8·5 and 22·7 percent respectively[11,12]. However, these trials were small, comprising only 93 patients and, more importantly, the mean follow-up period was only just over 3 years; a much higher local recurrence rate would be expected with time. Mastectomy could therefore represent over-treatment for many patients with ductal carcinoma *in situ* but in others lesser treatments may jeopardize the chance of cure.

Still to be defined is the effectiveness of adjuvant radiotherapy following excision biopsy, and this is the subject of a number of prospective trials in Europe and the USA. There are some uncontrolled data which suggest that radiotherapy does have an effect. In the National Surgical Adjuvant Breast Project[12], mastectomy was compared with excision biopsy with and without radiotherapy for invasive cancer. Of the 2072 cases recorded, 78 have been reclassified as ductal carcinoma *in situ*. In the 22 patients who underwent excision biopsy the local recurrence rate was 22·7 per cent but fell to 6·9 per cent (with no systemic failures) in the 29 patients who had excision and radiotherapy. A review of other studies confined to the role of radiotherapy after the excision of a palpable mass gives an overall local recurrence rate of 6·3 per cent in 150 patients with a 99 per cent survival rate, although yet again follow-up is too short to see the maximal number of recurrences.

Another problem associated with conservation therapy is that of multifocal disease referred to above. This is normally detected mammographically as widespread microcalcification, although studies on mastectomy specimens have revealed a high incidence of ductal carcinoma *in situ* whether or not it is radiologically determinable. The significance of this is difficult to determine, but it appears from the studies of Page *et al.*[3] that at least 30 per cent of such patients will be expected to develop local recurrence and half of these will be invasive cancer. It would seem logical, until more definite data have accrued from prospective trials, that those patients with widespread microcalcification and biopsy-proven ductal carcinoma *in situ* should be considered for mastectomy.The significance of residual disease following excision biopsy is probably similar. Although our own studies indicate that incomplete excision does not carry a higher recurrence rate than apparent complete excision, in practice we would recommend rebiopsy and, if residual disease is still present, mastectomy.

Failure to take part in clinical studies of invasive breast cancer and the inexplicable habit of clinicians of ignoring the results of these trials have resulted in a situation where a patient with breast cancer may receive treatment varying from radical mastectomy to lumpectomy, the decision often being made on personal prejudice. If we are not to repeat the same mistakes with ductal carcinoma *in situ* then we need the co-operation of trials organizations such as those funded by the Medical Research Council and Cancer Research Campaign to implement studies in which all breast screening centres should co-operate.

Technical aspects of war wound excision

R. M. Coupland

The British Red Cross Society, 9 Grosvenor Crescent, London SW1X 7EJ, UK

Correspondence to:
Mr R. M. Coupland

Excision of war wounds may be performed by civilian surgeons with no previous experience of war surgery. The principles of complete excision of non-viable tissue with removal of foreign material, leaving the wound open, and delayed primary closure of skin are vitally important. A major part of the surgical approach is wound assessment and the formation of an operative plan. The extent and ease of the operation depends on the site, age and type of wound. Attention to the technique of wound excision avoids septic complications and permits skin closure when the first dressing is removed. Wounds may need re-excision at a later date. Modification of surgical management is necessary when certain difficult areas are wounded and when the patient presents after many days or has suffered inappropriate first aid.

Keywords: War, wounds and injuries, débridement

The International Committee of the Red Cross (ICRC) has surgical hospitals for war wounded in six countries. The two largest are in Pakistan and Thailand for the wounded from the Afghan and Cambodian conflicts respectively. The hospitals depend on surgical teams from the National Red Cross Societies of many countries. Most of the surgeons are drawn from civilian practice and a mission with ICRC represents their only exposure to war wounds.

War surgery literature stresses the necessity of complete wound excision (débridement)[1,2]. That this is an easy surgical exercise is an assumption. In reality the operation is frequently performed inadequately. Excision of extensive wounds from, for example, a land mine is neither quick nor easy. Attention to the technique of wound excision reduces the number of operations, shortens hospitalization and in some cases saves lives and limbs. After resuscitation, the highest priorities are soft tissue healing and delayed skin closure which will not be achieved if the wound is not adequately excised. The efficiency of a field hospital is directly related to the adequacy of the wound excisions performed.

The ICRC has produced a film entitled *War surgery: an introduction*[3]. It shows real wounds, their excision and other aspects of wound treatment. It also shows the consequences of missing devitalized muscle at the time of wound excision. It stresses the basic and important principles of: excision of all non-viable tissue and foreign material, leaving the wound open, and delayed primary closure of skin.

For geographical and political reasons the ICRC hospitals are situated some distance from the battlefield. This results in some of the wounded presenting after days or weeks. The surgical management must be flexible to take into account the wound changes this delay produces.

Preoperative considerations

The wounded patient

A systematic clinical assessment of the wounded patient is essential. Important historical points are the type of weapon and the time since injury. Examination should detect signs of serious injury from penetrating missiles such as surgical emphysema around chest wounds. A full assessment of the wound may not be possible until plain radiographs have been taken and the patient is in the operating theatre and under anaesthesia.

The patient is resuscitated with intravenous fluids and cross-matched blood as appropriate. Patients seriously wounded more than 24 h before admission are usually anaemic and dehydrated but haemodynamically stable. Such patients rarely have to go to surgery immediately.

All patients with open wounds admitted to an ICRC hospital receive 5×10^6 units of benzyl penicillin, antitetanus serum and a course of tetanus toxoid.

Preoperative radiography

Plain radiography is a valuable part of wound assessment. The presence of a fracture changes the operative plan and post-operative care. Radiographs help to determine whether a severely injured limb can be salvaged or not.

Metallic foreign material indicates the nature of the weapon and the depth of penetration. The patient may not know how he was wounded. The absence of metallic material usually indicates a through and through wound. This should lead the surgeon to look for an inconspicuous entry wound. Alternatively, foreign material may not be radio-opaque. Pieces of shoe and mud are commonly present in wounds from antipersonnel mines and are particularly dangerous. Some such weapons have plastic fragments. The absence of metallic material does not indicate a less severe injury.

The radiographic presence of gas in the tissues does not necessarily indicate clostridial myositis which is obvious clinically and at operation. High velocity missiles are associated with palpable and radiographic intrafascial gas in healthy tissue some distance from the wound (*Figure 1*).

Anaesthetic considerations for the surgeon

The anaesthesia involved in the surgery of war wounds may be complex and demanding especially with wounds of the head, neck and chest. The extensive use of ketamine by ICRC anaesthetists is well recorded and is associated with few unpleasant side effects[4]. This is a safe anaesthetic agent and can be given to a hypovolaemic patient. The surgeon must be aware that it will make a normovolaemic patient hypertensive and that movement and phonation are not uncommon. Spinal anaesthesia for lower limb injuries is ideal, giving good operative conditions with hypotension.

It is essential that the surgeon and anaesthetist discuss the type of anaesthesia to be used, the position of the patient and the order of operation for multiple wounds. The surgeon must indicate the likelihood of a longer procedure, such as laparotomy or vascular repair, being needed.

The gas shadows outline the muscle groups.* **b** *Radiographs of an arm injured by gunshot. Intrafascial gas is seen but there was no reason to suspect gas gangrene at the time of wound excision. The patient made an uneventful recovery but surgical emphysema remained palpable for 5 days*

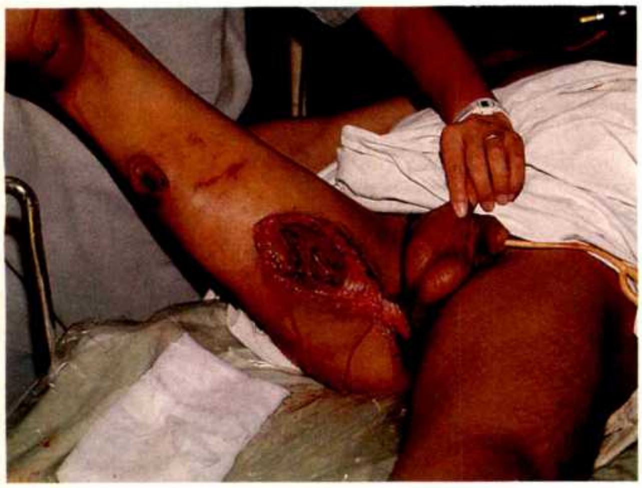

Figure 2 *Photograph of an injury of the right thigh. The entry wound, unseen, is high on the left buttock. The missile passed across the pelvis and made an exit between the anus and scrotum. It then entered the patient's right thigh (larger wound) and made its second exit slightly lower (smaller wound)*

Operative planning

When the patient is under anaesthesia a wound assessment is made by examination of the injured area or limb. The operation is planned accordingly. It is easy to miss a small wound which is the entry point of a high velocity missile. Such missiles can take long and surprising routes through the body (*Figure 2*).

Most wounds can be thought of as a cavity containing dead tissue which, with its skin margins, must be excised back to healthy tissue. Bearing in mind the mechanism of injury facilitates this concept.

Having assessed the wound the surgeon can predict the nature and extent of the operation. As a general rule the most severe injury possible should be expected as it is frequently encountered. For example, a missile which has penetrated the buttock should be expected to have entered the pelvis injuring rectum or bladder.

Limbs are involved in 73 per cent of war wounds[5]. A pneumatic tourniquet is invaluable in the initial surgery of distal limb wounds. Its application before removal of field dressing minimizes blood loss. The bloodless operative field then facilitates wound excision.

Wound excision

Operative technique

A basic set of instruments for wound excision includes a scalpel, large curved scissors, toothed dissection forceps, a curette, six haemostats and two medium-sized, lipped retractors. Diathermy is not necessary. Ligature material should be absorbable.

The skin is prepared with an antiseptic solution and the operative field draped in accordance with the operative plan. Drapes with holes should only be used for the smallest and most superficial wounds. The surgical wound is always larger than the initial wound.

As little skin as possible is removed. It is resilient tissue. Only that which is non-viable around the wound edges is excised. The wound can be enlarged further by appropriate incisions. Limb incisions should be longitudinal which allows decompression of viable muscle and easier visualization of damaged structures.

A thorough wound excision involves display of all structures in the wound 'cavity'. Individual muscles and tendons are dissected bluntly and their damaged part excised back to healthy tissue. Viable muscle is recognized by its colour, bleeding, texture and contractility. Heavily blood-stained and contaminated intermuscular fascia is excised. With through and through wounds the skin incisions and dissection are based on both entry and exit wounds (*Figure 3*) and if possible should meet. The exit wound is usually the larger.

When the wound includes a fracture, that part of the bone must also be displayed. Any small or unattached bone fragments

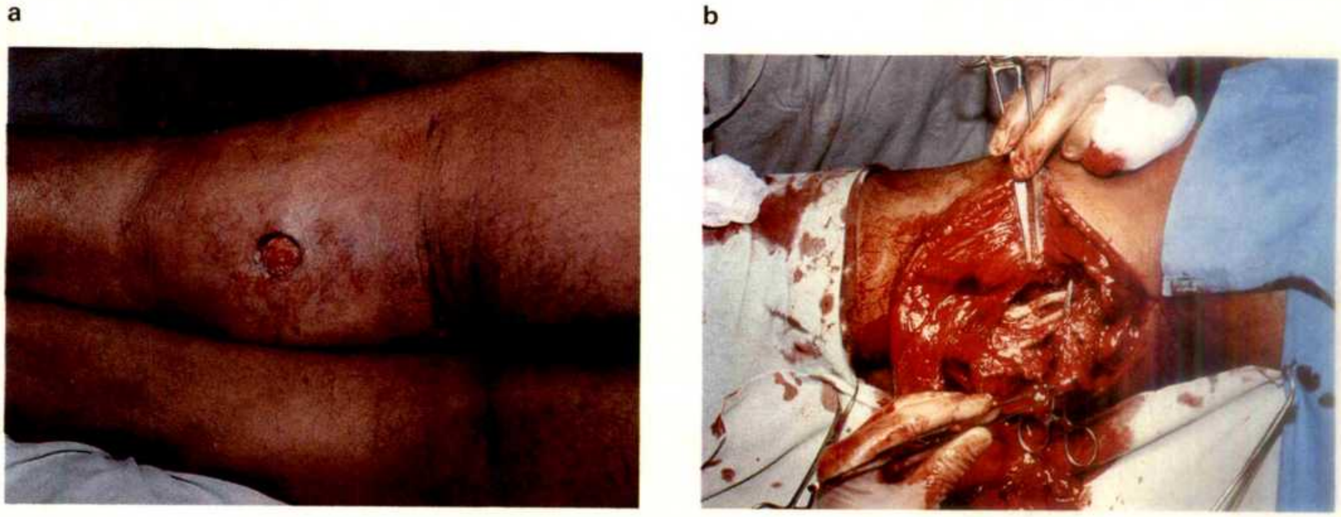

Figure 3 **a** *The posterior aspect of the left thigh and the exit of a gunshot wound 6 days after injury. A swab has been pushed into the wound at the time of injury.* **b** *The same wound in the process of excision. The lateral side of the wound has been excised. Non-viable muscle is still visible on the medial side of the wound*

must be removed. This may ultimately involve removal of a large segment of bone. Curettage of exposed medullary bone back to firm marrow is necessary. Bone left *in situ* is cleaned of dead muscle and foreign material. Unattached fragments left *in situ* act as a nidus for chronic wound infection and will not act as a bone graft. The priority is soft tissue healing.

As much foreign material as possible is removed. Small metallic fragments can be difficult to find and prolonged surgery to find them is unnecessary and dangerous. Only rarely do these cause problems. The foreign materials that must be removed because of their tendency to cause severe wound infection are: mud, pieces of shoe, cloth and extrinsic bone fragments[3,6]. The last of these are blown in from another person or another part of the patient and on radiographs can easily be mistaken for a fracture.

The wound is best judged as having been excised adequately by direct visualization and the surgeon's finger. Foreign material, loose bone fragments and, with experience, devitalized muscle can be felt in the wound depths. One should be able to see and feel that the excision is complete.

Haemostasis is achieved by ligation of vessels with absorbable material and compress application. The wound is liberally washed with saline. Antiseptic solutions at this stage are of no value. They do not excuse leaving dead or contaminated tissue and will not prevent infection of such tissue. The treatment of war wounds is surgical and not chemical.

Sutures for closure are never applied at this stage except to the face, scalp, dura, joint capsules and serous cavities.

The operative dressing is dry gauze, loosely fluffed, in sufficient quantities so that blood and serum will be taken up. Vaseline gauze or antiseptic dressings are not used. Gauze moistened with normal saline may be applied over exposed joints and tendons.

Pitfalls in wound excision

The consequences of missing dead muscle when excising a large wound are disastrous[3]. When a muscle group is injured only those individual muscles which are partially divided are visible in the wound. Those muscles completely transected contract away from the wound. Their devitalized ends must be exposed by adequate skin incisions and dissection.

The advent of the external fixator has facilitated the treatment of large soft tissue wounds associated with limb fractures. Wound excision is hampered by rigid fixation. The application of an exteral fixator has a lower priority than wound excision and so should be delayed until the first dressing 4 or 5 days later. If further wound excision is required it can be more easily performed before the fixation is applied. There is no need to immobilize the limb by means other than a plaster of Paris splint or skeletal traction in the first instance. By this regime external fixation is performed on a routine list and not as an emergency. Moreover the pin sites are theoretically likely to become infected if made when the patient has just been brought in from the field.

The fascial compartments below the knee are prone to the compartment syndrome, particularly the anterolateral compartment. The condition should be expected in any penetrating wound below the knee with or without a tibial fracture. A missile passing through a compartment can cause necrosis of the muscles therein without gross swelling of the limb. Open fasciotomy by incisions on both sides of the leg shows the extent of muscle devitalization and if performed early enough prevents further necrosis. The surgeon should be prepared to perform open fasciotomy at the time of wound excision. The degree of muscle necrosis can necessitate excision of all muscle in the compartment. This is a large wound but heals remarkably quickly (*Figure 4*).

Injuries of nerves and vessels

It is not within the scope of this review to describe the surgical approach to injured nerves and vessels. Attention is drawn to other texts which cover this subject[1,2,7].

Large nerves are resilient. They are often the only structure left running through the wound cavity. Although contused they should be left intact and the wound excised around them. Some recovery may be possible. There is no place for primary nerve repair at the time of wound excision.

When the patient survives injury to major vessels and the periphery is rendered ischaemic the affected limb is rarely salvageable. Reconstruction of vessels across a large wound cavity is difficult and must be covered by viable muscle if it is to succeed. Vascular injuries that can be repaired are usually caused by small fragments from shell or mine with minimal damage to surrounding structures. In an ICRC hospital, because of the delay in presentation most vascular injuries present as gangrenous limbs requiring amputation, pseudoaneurysms or arteriovenous fistulae.

Traumatic amputation

Traumatic amputation is a common injury especially of the foot or lower leg by a land mine. The surgeon must be aware that damaged tissue and earth may be pushed up within the fascial compartments (*Figure 5*). The surgical amputation is at a higher level and may resemble a thorough excision of the original

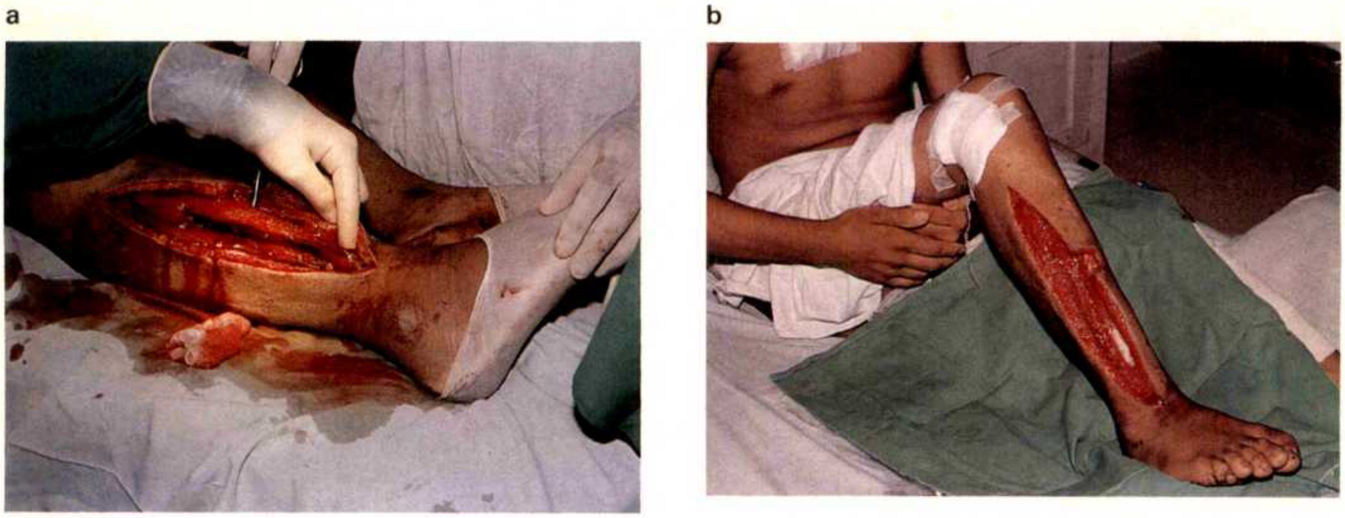

Figure 4 **a** *The lateral aspect of a leg injured by a shell fragment which passed between the tibia and fibula without fracture. The injury was 2 days old. The missile track is indicated by the artery forceps. The surgeon's finger shows necrotic extensor muscle some distance from the wound.* **b** *The wound seen in* Figure 4a *after 7 days of regular dressing and the day before closure by suture and skin graft*

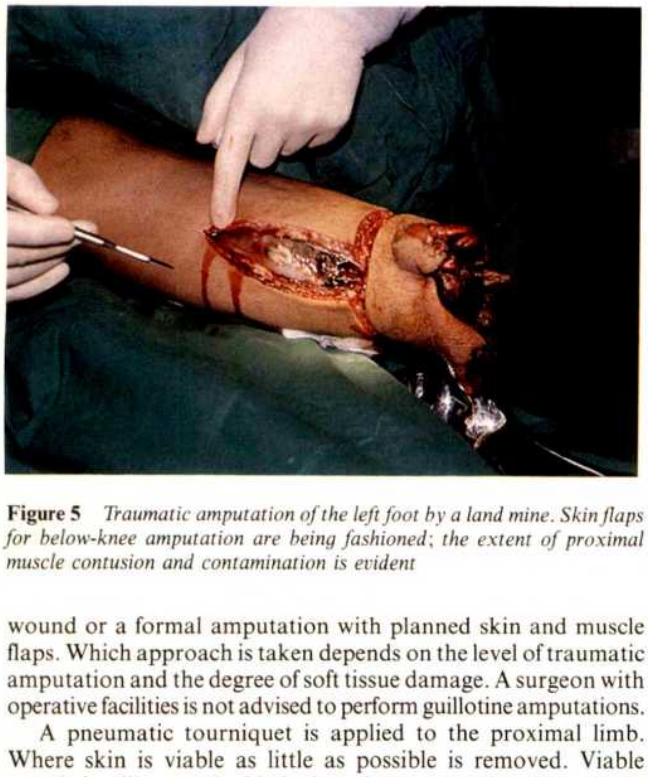

Figure 5 *Traumatic amputation of the left foot by a land mine. Skin flaps for below-knee amputation are being fashioned; the extent of proximal muscle contusion and contamination is evident*

wound or a formal amputation with planned skin and muscle flaps. Which approach is taken depends on the level of traumatic amputation and the degree of soft tissue damage. A surgeon with operative facilities is not advised to perform guillotine amputations.

A pneumatic tourniquet is applied to the proximal limb. Where skin is viable as little as possible is removed. Viable muscle is still recognizable by its colour, texture and contractility in a temporarily ischaemic limb. The bone and muscle sections are made to excise devitalized and contaminated muscle and to permit delayed closure of the remaining skin.

After performing above-knee amputation, release of the thigh tourniquet causes muscle to retract in relation to the bone and skin flaps. This must be remembered when planning the level of skin and muscle section.

It is rare to be able to perform a below-knee amputation with a long posterior myocutaneous flap. The wound is usually such that the soft tissues on the back of the leg must also be excised. Equal skin flaps are usually the sole option.

Principal vessels are transfixed with an absorbable suture. Haemostasis must be achieved after release of the tourniquet.

The surgical amputation is left open, with no sutures applied, and delayed suture is performed after 4 or 5 days when soft tissue can be trimmed. Failure to achieve this is due to the remaining skin being too short in relation to the bone section. In the period between surgical amputation and delayed suture the skin retracts up the stump and the exposed muscle swells. An amputation which looks as though it would close easily at the time of operation may only do so with further trimming of bone and muscle. A suction drain should be placed beneath the skin flaps when the delayed suture is performed.

Re-excision of wounds

Some time after the initial wound excision it may become apparent that this was incomplete. In the early days, temperature, excessive pain and copious purulent discharge into the dressings are indications to return the patient to theatre. The wound is reassessed and any remaining devitalized tissue is excised.

After many days or weeks failure of a wound to heal or visible bone indicate that more soft tissue or bone has to be removed. A degree of healing will have occurred around the wound which remains a cavity containing non-viable tissue, bone fragments or protruding ends of fractured long bones. Access to this cavity may be difficult. The only course is to reincise the skin, curette the cavity and excise dead bone ends with powerful bone nibblers. When the re-excision is complete, digital examination confirms a smooth cavity free of bone ends and fragments. This cavity will slowly heal in by secondary intention and ultimately callus will form across it.

Factors modifying the technique of wound excision

Areas where wound excision is difficult

There are areas of the body which when injured do not lend themselves to wound excision. Aggressive excision of all non-viable tissue from these areas would result in loss of the patient's life or irreversible loss of function of that part. Such areas, in the author's experience, are the neck and parapharyngeal spaces, the retroperitoneum and the pelvis. As in other branches of surgery, the operator must accept that complete excision of some lesions will result in massive blood loss and an irreparable defect. The best that can be achieved is the repair or avoidance of vital structures, haemostasis and, if the patient survives, repeated wound toilet.

Another area of particular difficulty is the tarsus because gaining access to all damaged tissue and bone fragments would involve complete tarsal disruption. Repeated vigorous curettage along the track is recommended.

A penetrating war wound of the abdominal wall is an indication for laparotomy. The wound is rarely a problem in comparison to the visceral damage. The visceral surgery most commonly involves intestinal repair or resection with proximal diversion or exteriorization when the colon is involved. Liver injuries are frequent and usually require suture haemostasis only. After laparotomy the wound itself is excised and if possible the peritoneum is closed. An abdominal wound including a left-sided large bowel injury usually involves that part of the abdominal wall preferred for the stoma. This problem can be overcome by colonic mobilization and bringing out the colostomy in an unconventional site. Colostomy through an abdominal wall wound is not recommended.

Inappropriate first aid

Despite the lessons that have been learnt this century, practitioners of first aid in countries at war continue to suture war wounds primarily. Wounds sutured in the field invariably putrefy and should be completely excised even if the skin has apparently healed[6]. The wound is left open as described above and resutured after 4 or 5 days.

Field tourniquets applied high on a limb many hours or even days before present the surgeon with a dilemma. Should he release the tourniquet, excise the wound and risk renal failure from myoglobinaemia or should he amputate above the tourniquet? A reasonable guideline might be that if there has been complete vascular occlusion for more than 6 hours then he should amputate proximal to the tourniquet.

Old wounds

Many of the injured with whom ICRC is concerned travel for a long time before reaching medical aid. An ICRC surgeon's experience of the effects of modern weaponry differs markedly from that of his military counterpart who receives the wounded soon after injury. This delay necessitates changes from conventional management. The wound may require more aggressive surgery because of putrefaction or gangrene. Alternatively the wound assessment may reveal that the wound has started to heal and so a less aggressive surgical approach may be taken[6].

Operative blood loss when excising an old wound may be great because the surgeon is working through oedematous and inflamed tissues. It can be difficult to identify viable muscle under these circumstances.

The nutritional status, anaemia and dehydration of a patient with putrefied wounds inevitably lead to poor healing after wound excision. This necessitates a longer period before delayed suture.

Dressings

After wound excision the operative dressing is left for 4 or 5 days and removed in the operating theatre with the patient under anaesthesia. When correct wound excision has been performed the muscle adheres to the adjacent gauze and contracts away as the dressing is gently peeled off. The wound is then ready for suture or skin graft. If there is pus or evidence of dead muscle the affected part of the wound must be more widely excised and again left open with gauze dressings.

To leave the dressing undisturbed for 4 or 5 days requires confidence in the initial wound excision. Further confidence is needed when the dressing is soiled and offensive after 2 or 3 days. Providing the patient remains well and apyrexial such a dressing should be left undisturbed until the set date. The state of the dressing is no indicator of the state of the wound especially in a field hospital in a hot country.

At the time of first dressing change a wound is occasionally seen which has a light seropurulent discharge yet all the tissues are viable. This requires further dressing every day or two until clean enough to close. In such a case an antiseptic such as a weak sodium hypochlorite solution may help.

Delay of closure beyond the first dressing change

Closing the wound on the fourth or fifth postoperative day is recommended on the assumption that the patient is a fit young person with a non-infected, completely excised wound. If the wound is not clean or was infected before initial surgery an extended period of dressing may be required before closure. A large wound may need longer before it will accept a split skin graft.

Those patients presenting after several days may need their skin closure delayed further. It is wise to plan this if the patient is anaemic, or his nutritional status is poor. In these circumstances an apparently clean wound, when sutured, can fail to heal.

Ileitis and pouchitis after colectomy for ulcerative colitis

A. D. Scott and
R. K. S. Phillips

Professorial Surgical Unit,
St. Bartholomew's Hospital, West
Smithfield, London EC1A 7BE, UK
Correspondence to: Mr A. D. Scott

Ileitis can occur after surgical treatment of ulcerative colitis. Following continent ileostomy or restorative proctocolectomy ileitis can become a serious clinical problem and is then known as pouchitis although this condition is yet to be clearly defined. It is likely that pouchitis is the result of an abnormal host response to a change in bacterial flora and that the nature of this host response is related to the underlying pathogenesis of ulcerative colitis. Continued study of the immunological basis of ulcerative colitis is therefore required to solve the problem of pouchitis.

Keywords: Ulcerative colitis, surgery

'Pouchitis' is a term coined by Kock *et al.*[1] to describe the reservoir ileitis that occurred in a number of his patients with ulcerative colitis who had undergone the operation of continent ileostomy. He had first reported this procedure[2] in five patients in 1969 and since that time there have been numerous descriptions of pouchitis in the literature.

In 1980 the operation of proctocolectomy with ileal reservoir and anal anastomosis was described by Parks *et al.*[3] and it became clear that this operation, when performed for ulcerative colitis, also produced pouchitis in a number of patients. The aetiology of pouchitis is uncertain but there are a number of situations in which ileitis can occur after surgery for ulcerative colitis.

Ileitis following colectomy and conventional ileostomy

In the 1940s and early 1950s the development of ileitis in the terminal ileum immediately proximal to the ileostomy following the operation of colectomy was recognized as a serious and not uncommon complication of the operation[4]. It was on occasion associated with perforation of the diseased small bowel in the early postoperative period and this complication was initially felt to be due to placing the ileostomy too close to the caecum in the site of preoperative 'backwash' ileitis[4–7]. A type of ileitis was then described[8] which could be relieved by stomal dilatation and lavage with a catheter, and it became widely accepted that postcolectomy ulcerative disease of the ileum was secondary to chronic ileostomy obstruction (dysfunction) and was reversible if the obstruction was removed[8,9].

Since the introduction of the Brooke or Crile–Turnbull techniques of ileal eversion and primary mucocutaneous suture, ileostomy obstruction due to early oedema or late fibrosis has become rare, as has ileitis following colectomy for ulcerative colitis. However, it does still occur[10–12] and usually requires further operation and ileal resection. It may well be that in at least some of these patients this complication is in fact due to the existence of Crohn's disease.

Ileitis in the reservoir of Kock's continent ileostomy

In 1969 Kock described an operation in which an intra-abdominal reservoir and 'continent' ileostomy were constructed[2]. By 1976 he had performed 164 of these operations but had encountered non-specific ileitis in the reservoir of 14 patients. These had all been successfully treated by catheter drainage and sulphasalazine[13] and it was felt that the mucosal inflammation was due to stasis and overgrowth of anaerobic bacteria[1]. Other authors[14] reported that the incidence of this complication varied from 13 to 43 per cent and that it was not a problem in pouches constructed for familial adenomatous polyposis[15]. However, mucosal biopsies of all reservoirs showed histological evidence of inflammation and this was more severe in the ulcerative colitis patients. Clinically, pouchitis causes bloody diarrhoea associated with abdominal cramps and occasionally fever[16]. Most authors agree that conservative treatment is usually successful although removal of the reservoir is sometimes necessary[17].

Other patients sometimes develop troublesome diarrhoea without evidence of mucosal inflammation[18,19] and the incidence of this problem varies from 7·5 to 32 per cent. This clinical picture may be related to a change in bacterial flora and comparison of conventional ileostomy effluent, intra-abdominal reservoir content and normal faeces has shown differences in both the numbers of micro-organisms and the ratio of aerobes to anaerobes[20]. The most frequently isolated anaerobes were *Bacteroides*, clostridia and anaerobic streptococci, and the bacterial constitution of ileostomy reservoir content seems to hold an intermediate position between conventional ileostomy effluent and normal faeces. Micro-organisms are known to be potent producers of metabolites and toxins which could lead to changes in the ileostomy reservoir, and by consuming essential substances from the intestinal contents the bacteria could possibly impair absorption[20].

Other studies have indeed shown that vitamin B_{12} absorption is reduced in patients with a continent ileostomy when compared with those with a conventional ileostomy[21]. Steatorrhoea was also reported, and in four of seven patients with a continent ileostomy there was evidence of a stagnant loop syndrome as oral lincomycin treatment resulted in increased absorption of B_{12}, decreased excretion of faecal fat and decreased concentrations of *Bacteroides* in the ileum[21]. Changes in the amount and composition of bile salts in the ileostomy reservoir have also been reported[22].

Certain morphological changes appear to take place in the mucosa of an ileostomy reservoir[23]. There is a decrease in villus height but an increase in the number of crypt cells and mucosal

0007-1323/89/070668–02$3·00 © 1989 Butterworth & Co (Publishers) Ltd

volume. During the first year after operation the epithelial turnover increases, but after 6–10 years turnover seems to normalize In this study there were no signs of alarming changes such as dysplasia or progressive atrophy, and the morphological changes may represent adaptation of the mucosa to the change in luminal bacterial content.

Ileitis in the ileal reservoir following restorative proctocolectomy

The desire to avoid a permanent ileostomy in patients requiring surgery for ulcerative colitis or familial adenomatous polyposis has led to the development of the operation of restorative proctocolectomy. This was initially described in experimental models both with[24] and without[25] an ileal reservoir Parks *et al.*[3] reported the clinical results of proctocolectomy with ileal reservoir and anal anastomosis in 1980, and it is now well established that the addition of an ileal reservoir produces better results than a straight ileoanal anastomosis[26,27]

The commonest complications of the procedure include intestinal obstruction, pelvic sepsis, anastomotic dehiscence and stenosis However, inflammation in the reservoir is common, although most cases are subclinical in fact, chronic inflammation has been found in up to 90 per cent of patients[28]. Pouchitis is characterized by acute inflammation with endoscopic changes and frequent, loose stool and occurs in between 8 per cent[29] and 20 per cent[30] of patients. Its occurrence does not appear to be related to the type of reservoir or the residual volume, suggesting that stasis is not a major factor, but it is much commoner in those patients with a diagnosis of ulcerative colitis.

The faecal flora of pouches contains a greater predominance of anaerobes and increased numbers of *Bacteroides* compared with the faecal flora of ileostomies[31], and similar histological changes have been demonstrated in pouches as occur in Kock's intra-abdominal reservoirs[32]. Although in some cases pouchitis is a very serious complication, occasionally requiring removal of the pouch, most authors still agree that episodes of pouch inflammation are usually successfully treated with metronidazole[33,34]. The usefulness of metronidazole in this context may be because of its immunosuppressive[35] rather than its antibacterial activity, but is of interest as the drug does not appear to have a role in the treatment of ulcerative colitis[36].

In conclusion, it is therefore apparent that non-specific ileitis can occur after colectomy for ulcerative colitis whether a conventional ileostomy, continent ileostomy or pouch operation is performed. As this does not occur after surgery for familial adenomatous polyposis, it is likely that the aetiology of reservoir ileitis or pouchitis is related to the aetiology and pathogenesis of ulcerative colitis rather than any purely mechanical effect of the reservoir itself.

Although the changes in bacterial flora may be secondary to stasis and themselves give rise to the histological changes in the mucosa, the problem of pouchitis is not just a histological phenomenon and is unlikely to be solved until the pathogenesis of ulcerative colitis itself has been more fully elucidated.

This review examines the evidence that tumour necrosis factor is the principal mediator of the derangements associated with severe sepsis.

Keywords: Cytokines, bacterial sepsis

Sepsis in surgical patients is associated with a constellation of responses which include fever, hypotension, tachycardia, anorexia, fluid retention, electrolyte abnormalities and hyperglycaemia. If the infection is prolonged, anorexia and increased breakdown of adipose and lean tissue occurs, and these alterations may progress to single or multiorgan failure. In the past these host responses to infection have been attributed directly to the effects of toxins from invading bacteria or to the presence of widespread tissue destruction However, it is now recognized that the host itself generates signals that result in these adverse responses[1,2]

There is now increasing evidence that the primary afferent signal generated by the host that leads to many of the changes associated with life-threatening sepsis is the cytokine tumour necrosis factor (TNF/cachectin), a 17 000 molecular weight polypeptide produced by stimulated reticuloendothelial cells, principally macrophages and monocytes[3]. This cytokine was named tumour necrosis factor because of the history of its isolation and characterization At the end of the last century, William Coley, a New York surgeon, demonstrated that the injection of certain bacterial products locally into oropharyngeal tumour sites induced tumour regression[4]. In 1975 Carswell *et al.* demonstrated that a soluble factor released by the host after exposure to bacterial endotoxins was responsible for tumour cytotoxicity, and this factor was termed tumour necrosis factor[5]. Only when the amino acid sequence of the molecule was determined was it realized that this substance was identical to cachectin, a newly discovered macrophage product, which was believed to cause adverse host responses to bacterial invasion.

The purpose of this review is to examine the evidence supporting the hypothesis that TNF is a principal host mediator of the derangements associated with severe sepsis.

To demonstrate a cause–effect relationship between a molecule and any putative effects it may have *in vivo* requires that a series of experiments be performed to answer specific questions, similar to those posed by Koch who was faced with the same difficulties when attempting to prove the association between micro-organisms and disease[6]. The first requirement for such a proposal is that the molecule can be demonstrated in the circulation at the time when host responses are initiated. Early attempts to demonstrate the presence of circulating TNF gave inconsistent results in that TNF was not generally detected in the plasma of patients with established sepsis[7]. A major exception to this was the finding that circulating TNF was almost invariably demonstrated in the plasma of patients dying of meningococcal septicaemia[8,9]. These observations led to the suggestion that TNF might be released as a single pulse, following an appropriate provocative stimulus, to produce biological effects that far outlive its survival at detectable levels in the bloodstream. Thus, by the time that symptoms become established the molecule has already initiated the responses and is no longer detectable by conventional techniques.

This hypothesis has been tested in baboons receiving lethal injections of live *Escherichia coli* organisms. TNF was always present in the circulation at the onset of shock but disappeared from the circulation several hours before death[10]. The pulsatile nature of TNF release has been confirmed in studies involving healthy humans receiving bolus intravenous injection of *E. coli* endotoxin. TNF was present in the circulation 90–180 min after endotoxin administration and its first appearance was associated in time with the onset of symptoms, fever, tachycardia and neurohormonal responses. Furthermore, the magnitude of TNF-release following a standard dose of endotoxin predicted the extent and duration of the ensuing clinical and metabolic responses in these subjects[11]. These studies provide strong evidence that although TNF cannot generally be detected by the time that life-threatening haemodynamic instability has developed, it is present shortly after bacterial invasion occurs, during the prodromal period. The same studies showed a marked variation between individuals in the magnitude of TNF-release following a standard dose of endotoxin This observation may, in part, explain the well recognized variation between individuals in terms of their symptoms and the pyrexia and cardiovascular responses observed during infections of comparable severity.

The demonstration of TNF in the circulation at the onset of critical illness does not, of course, prove a causal relationship between the molecule and the symptom complex. Recently TNF has been manufactured to a high degree of purity using recombinant technology When recombinant human TNF (rH-TNF) was administered in lethal doses to rodents it produced circulatory collapse and death. Post-mortem findings were indistinguishable from those observed after death from septic shock[12] Dogs receiving sublethal infusions of rH-TNF developed the full spectrum of changes associated with sepsis, including fever, hypermetabolism, hypotension, acidosis and increased pituitary and stress hormone elaboration[13]. When rats received chronic (5-day) infusions of rH-TNF, profound anorexia and fluid retention were also observed[14]. Recently, rH-TNF has been given to humans in clinical trials as a potential antineoplastic agent. The physiological responses that occurred following acute (24-h) infusions were strikingly similar to those occurring following endotoxin administration when the peak plasma TNF levels in the two situations were similar. Responses following rH-TNF infusion occurred more rapidly than following endotoxin, presumably because a latent period was required by the host after endotoxin administration to synthesize and release TNF[15]. When rH-TNF was infused at lower doses over 5 days to humans, fever, marked anorexia and fluid retention consistently occurred[14]

The final evidence that TNF is a principal mediator of

0007-1323/89/070670-02$03 00 © 1989 Butterworth & Co (Publishers) Ltd

adverse host changes during sepsis comes from studies in animals where the effects of TNF are neutralized. Mice of the C_3H/HeJ strain have long been known to be resistant to otherwise lethal doses of bacterial endotoxins. It has recently been demonstrated that this strain of mice has a genetic defect that prevents the synthesis and release of TNF[16]. Endotoxin-sensitive mice pretreated with neutralizing anti-TNF antiserum develop marked resistance to lethal doses of endotoxin[17]. Similarly, baboons receiving lethal (LD_{100}) doses of live *E. coli* organisms invariably survived when pretreated with monoclonal neutralizing anti-TNF antibodies[18]. Thus, although a large number of mediators are clearly involved in the cascade that leads to full-blown septic shock, these data suggest that the outcome pivots on the production or otherwise of excessively large amounts of TNF by the host.

These studies have major implications for the development of future strategies to modify the course of severe sepsis in surgical patients. Because TNF is released as a brief pulse following infection, attempts to block its biological effects will generally be likely to be successful if blocking agents are administered very early in the course of the disease, and not when clinical manifestations of septic shock are maximal. Glucocorticoids are potent inhibitors of TNF synthesis and release[16], but this therapy has only proved to be beneficial when these agents were administered to shocked patients almost immediately on arrival in hospital and before any diagnosis was made[19]. Steroid administration later in the course of septic shock has failed to show any benefit[20] and it is possible that the timing of steroid administration in relation to the time at which maximal TNF elaboration occurs following bacteraemia might well explain the discrepancy between results obtained from different groups. It is arguable that similar considerations will apply to the use of monoclonal neutralizing antibodies against TNF.

There is now, however, good evidence that many of the effects of TNF occur through local and systemic activation of the cyclo-oxygenase pathway: many of the reactions that occur following TNF administration *in vivo* are attenuated by inhibitors of the enzyme arachidonate cyclo-oxygenase[11,21]. The initial evidence in both animals and humans suggests that the use of such agents modifies the adverse host responses following injury or infection and diminishes many of the deleterious events associated with TNF elaboration[21–23].

Clinical trials are urgently required to determine if these extraordinarily interesting experimental observations can be translated into improved survival of our critically ill surgical patients.

In a mammography screening programme for the early detection of breast cancer 66 cases of ductal cancer in situ *of the breast (DCIS) were diagnosed between 1978 and 1984 and prospectively followed up. In the beginning of the study period, DCIS was treated by mastectomy without axillary clearance but sector resection has been performed increasingly. Since 1982 the latter procedure has become standard treatment. Radical resection was confirmed by specimen X-ray and histopathological examination of whole organ sections. No postoperative radiotherapy was given. Twenty-eight women had mastectomy and 38 had sector resection. The median follow-up times were 77 and 60 months respectively. In the mastectomy group postoperative monitoring did not reveal any local recurrence but one contralateral new invasive cancer was discovered. In the sector resection group five recurrences were found. Three of the latter were new cases of DCIS and two appeared as small invasive cancers (stage I). Mastectomy will cure ductal cancer* in situ *but has a greater morbidity. Sector resection has been established as the method of choice in stage I invasive cancer and is probably also safe in DCIS. The possible beneficial effect of postoperative local radiotherapy after sector resection for DCIS is currently being analysed in a randomized trial which started in Sweden in 1987.*

Keywords: Breast cancer, ductal cancer *in situ*, occult breast cancer, mammographic screening

When mammography was offered on demand to a large fraction of the female population, the number of non-palpable mammary gland malignancies found increased. Since our mammography screening programme started in 1978 this situation has been even more pronounced. Of those malignancies found by mammographic screening, about 10 per cent are ductal cancer *in situ* (DCIS)[1], mostly reported as non-palpable lesions. The question of which is the best treatment for DCIS has not yet been answered. Most data have been collected from the re-evaluation of old biopsy material or reported as the results of treatment by mastectomy[2–4]. Another reason for the controversy concerning the treatment of DCIS is that the histopathological picture is difficult to interpret in some of these lesions. Microinvasive DCIS and some cases of big DCIS of comedo type have probably previously been allocated to the ductal invasive cancer group.

The treatment of all types of breast cancer has by custom been mastectomy, but now stage I cancers and, more recently, stage II cancers are treated with breast-conserving procedures such as sector resection or quadrant resection, mostly with adjuvant radiotherapy. This treatment has also been tried on DCIS lesions. DCIS is only rarely found by clinical examination without the aid of mammographic screening, and therefore individual clinics usually have little experience in the treatment of this type of cancer. Studies of DCIS have therefore to be done on a multicentre basis. Work has already started with the National Surgical Adjuvant Breast and Bowel Project (NSABP) and the European Organization for Research on the Treatment of Cancer (EORTC) programmes in some centres. A similar Swedish multicentre study regarding breast-preserving treatment with or without radiotherapy started in 1987.

The present paper reports the recurrence rate after conservative or ablative surgical treatment of DCIS as seen in a 6-year prospective study.

Patients and methods

Between 1978 and 1984, 66 cases with DCIS were discovered through the current mammographic screening programme in the county of Östergötland, Sweden. The screening procedure is one oblique view mammogram, a short questionnaire about breast disorders answered by the woman, and an inspection of the breast by the X-ray assistant.

All 66 lesions were analysed by mammography and clinical examination, and 44 were further evaluated by fine needle aspiration cytology. When our screening programme started in 1978, mastectomy without axillary exploration was considered to be the treatment of choice for DCIS When breast-conserving procedures became accepted for stage I breast cancer, we also gradually began treating DCIS in the same way, and since 1982 sector resection has been our standard treatment for DCIS[5].

Twenty-eight lesions were treated by mastectomy and 38 by sector resection. No radiotherapy was given Non-palpable lesions in the sector resection group were labelled preoperatively with a needle under mammographic control and a peroperative specimen X-ray was routinely carried out[6].

The excised lesions were histopathologically evaluated after whole organ sectioning[7]. An accurate diagnosis can be made by this technique together with the confirmation of tumour-free margins and the extent of the lesion. Tumour-free margins were stated to be 10 mm, and if the margins were not free or a resection margin was close to a DCIS lesion further surgery was performed. This happened in ten cases Two main types of DCIS are found comedo and cribriform. Patients with microinvasive tumours were excluded from the material The remaining 66 cases represent pure DCIS of the comedo type ($n=32$) or of the cribriform type ($n=34$).

The median follow-up time was 77 months (range 48–106) and 60 months (range 25–100) in the mastectomy and sector resection groups, respectively Five older patients in the mastectomy group died recurrence-free within 2 years of operation and are excluded from the calculation of follow-up time Follow-up was performed as a clinical examination at 6-monthly intervals between 1979 and 1982 and thereafter annually. Mammography was carried out once a year. When recurrences were found, those patients with pure DCIS were treated by

0007-1323/89/070672–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

further sector resection while patients with invasive cancer were offered mastectomy.

Results

The diagnosis of DCIS was reached by a combination of mammography, cytology and clinical evaluation, and verified histologically in 66 patients having a mean age of 61 years (range 40–87).

Mammography

The cases were allocated to five groups depending on degree of malignant appearance. Out of the 66 cases, mammography was declared normal or benign in eight; 24 of the lesions were judged as probably malignant or malignant and 34 had an 'equivocal' mammogram (*Table 1*).

In the majority of cases microcalcification was the dominant pathological finding whereas fibrosis with disturbed architecture was present only in a limited number of cases (*Table 1*).

Cytology

Out of 44 cases in which cytology was performed, 32 were judged to show malignant cells (*Table 2*). Cases with a malignant diagnosis generally represent DCIS of the comedo type. In six cases benign lesions or lesions with slight atypia were observed, whereas the remaining six cases showed atypia.

Clinical findings

In ten cases the lesions were palpable. DCIS was present together with Paget's disease of the nipple in eight cases (*Table 3*). Two patients with palpable tumours and two with Paget lesions had normal mammograms but the presence of a neoplastic lesion was picked up by the questionnaire and the inspection. In four cases the palpable lesions contained mostly fibroadenosis together with the DCIS. A Paget's lesion was present together with a palpable mass in only one case. Blood from the nipple was present in one case with a non-palpable DCIS.

11–20	12	14
21–30	1	3
31–50	5	1

Multifocality. Multifocal DCIS, defined as lesions more than 5 mm apart, was found in 11 cases (*Table 4*). Another four cases also showed lobular cancer *in situ* in parallel with DCIS. Three cases were referred for mastectomy because of the presence of more than three foci of DCIS, but another three with more than three foci still had sector resection as the final treatment.

Size. DCIS foci closer than 5 mm are regarded as one lesion of DCIS, the extent of which is given as the largest diameter (mm). The majority of the lesions had an extent between 11 and 20 mm (*Table 5*). Six cases were between 31 and 50 mm and eight had lesions smaller than 5 mm.

Primary reoperations for radical therapy

Three patients, who were initially offered breast-conserving therapy, were subsequently treated by mastectomy owing to the presence of multicentric DCIS with uncertain margins found at the primary operation. These patients were accurately treated by the mastectomy and are reported in the mastectomy group. Seven lesions in the sector resection group had an uncertainty expressed about the margins and a second resection was done to guarantee clear margins.

Free margins in the sector resection group

After surgery and primary reoperations in the sector resection group, 25 patients had a free margin ≥10 mm, five had a margin of 5–9 mm and another eight had a tumour-free margin of <5 mm.

Follow-up

In total, six cases of recurrent breast malignancy were diagnosed during the follow-up period. These cases were detected by mammography. No case was clinically recognized by palpation

In the mastectomy group, one contralateral ductal invasive cancer (6 mm) was found after 53 months. No local recurrence was observed.

In the sector resection group five relapses (13 per cent) were diagnosed at follow-up. The nature of the primary lesion, the type of relapse and the time interval between the primary and secondary lesion are given in *Table 6*. In three of the cases the primary lesion was DCIS of the comedo type, and in two it was of the cribriform type. Three of the secondary lesions were classified as DCIS, and two were invasive ductal cancers, all but one appearing in the same area as the primary lesion. Three of the recurrences developed in patients with a tumour-free margin of <6 mm.

Monofocal DCIS relapses were treated by a second sector resection whereas multifocal DCIS (case 5) and invasive lesions were treated by mastectomy. In one case of DCIS (case 3) two relapses at different times were found. After the second relapse mastectomy was performed.

DCIS, ductal cancer *in situ* of the breast

Discussion

DCIS is a malignant change in ductal epithelial cells that, by definition, does not penetrate the basal membrane of the mammary ducts. Minor areas of invasive growth may be difficult to detect and the diagnosis must be based on repeated sectioning of the specimen. The whole-organ sectioning technique is especially valuable for the diagnosis of DCIS[7]. DCIS lesions are often multifocal but rarely bilateral. A number of reports indicate a significant fraction of residual multifocal DCIS (about 30–40 per cent) or invasive carcinoma (10–20 per cent), as shown by examination of mastectomy material after breast biopsy or wide excision including the DCIS[3,8–12]. When the DCIS is multifocal, mastectomy is often proposed as being the treatment of choice at least as far as clinical DCIS is concerned. The problem, however, is that we do not know the frequency with which residual DCIS appears as clinically malignant, especially in DCIS discovered by a screening procedure. This is exemplified in a consecutive autopsy case series in which Nielsen *et al.*[13] found 11 cases of DCIS and invasive cancer in 77 women in whom there was no history of previous breast malignancy.

In the present case series, detectable multifocal lesions were found in 11 out of 66 cases (17 per cent). When relapses representing either simultaneous non-detectable malignant cell clones or metachronous lesions are included, five plus one (one case with two recurrences) more lesions are included, giving a total of 17 multifocal lesions in 66 patients (26 per cent) in an approximately 5-year perspective.

With the advent of mammography the ability to detect small malignant lesions has added a new dimension to the subject of disease of the breast In addition to problems regarding the morphological diagnosis of small lesions, including the interpretation of mammographs and fine needle aspiration samples, the variation in biological aggressiveness is probably greater in these occult tumours than in clinically obvious cancers, and is a dilemma for clinical judgement. Until appropriate biological tests are available, all these lesions must be regarded as potentially lethal.

The difficulty in reaching a positive diagnosis is reflected by the fraction of negative findings in both mammography and fine needle aspiration biopsy. Thus, in 58 of 66 cases (88 per cent) and 38 of 44 cases (86 per cent), a malignancy was suspected by the preoperative work-up with mammography and cytology, respectively.

In the present case series 58 per cent of the patients were treated with sector resection and the remainder with mastectomy. In 34 of 56 cases (61 per cent) lesions <20 mm were treated with sector resection (*Table 5*). This procedure was also chosen in two out of three of the cases where only one focus was diagnosed as malignant (*Table 4*) and where the lesions were non-palpable (*Table 3*). Mastectomy was more often employed when two or more malignant foci were observed (eight of 11) and when the tumours were >21 mm (six of ten). The choice of surgical treatment is probably influenced by several factors, including the relationship between the size of the lesion and that of the breast, the surgeon's experience as well as the patient's wishes and, furthermore, by the fact that mastectomy was standard treatment at the beginning of the screening period. Only three patients were converted to treatment by mastectomy. The variation in treatment further reflects the lack of information from prospective randomized case series regarding the various treatments available for DCIS.

Postoperative follow-up including mammography has shown that patients in the mastectomy group were free of disease in 27 of 28 cases (96 per cent) during the follow-up period, whereas the corresponding figure for the sector resection group was 33 of 38 (87 per cent) during their somewhat shorter postoperative observation. Previous studies[14–16] have indicated a relapse rate of up to 67 per cent over a 20-year follow-up period for clinical DCIS

The present case series shows that patients with DCIS run a risk of about 13 per cent of having a recurrence within 5 years if sector resection is chosen as treatment of the primary lesion. This risk must be weighed against the psychological morbidity of losing a breast where the risk of recurrent disease is practially nil. Size of tumour-free margin is probably an essential point to consider. In our material 13 of 38 cases had a margin less than that stated in the written protocol, and three of the recurrences appeared in this group. The present policy of making a wide sector resection around a monofocal DCIS is probably the method of choice in most cases of DCIS, but information from future prospective randomized studies may change this attitude. The benefit of adjuvant radiotherapy is implicated by the NSABP results[17] published in 1986.

Although Bloodgood[18], as early as 1936, wrote a paper where the potentially benign course of intraductal breast cancer was postulated, there is still no scientific evidence to indicate which treatment should be used for the various types of DCIS. Furthermore, it is important to evaluate information from cytometric and steroid receptor analyses to obtain a better basis for selection of patients in which a more aggressive initial treatment should be chosen.

In our opinion, relapses of monofocal DCIS can be treated by a further sector resection. A second relapse of DCIS can perhaps be prevented by irradiation of the remaining breast tissue at the time of the first recurrence. A relapse with invasive cancer in the same area as the primary DCIS lesion may be treated similarly, i.e. a new sector resection plus radiotherapy, even if mastectomy was performed in our two relapses of this type. If the lesion is multifocal or has an invasive component in another quadrant, mastectomy should be offered to the patient. This treatment for local recurrences is currently being investigated in the Swedish multicentre DCIS trial started in 1987.

F75012 Paris, France

Three hundred and thirty-five patients with high-output enterocutaneous fistulae arising from the small intestine are reported. Median fistula output was 1350 ml/24 h. Eighty-two per cent of patients were referred from other institutions. The fistula opening was associated with evisceration in 165 cases (49 per cent). One or more severity factors were present in 75·5 per cent of the patients. Patients were divided into three groups according to their initial therapy: 21 patients (6 per cent) referred in a moribund state were not operated on (non-intervention); 80 patients (24 per cent) were operated on as an emergency, and the fistula was either exteriorized or defunctioned; 234 patients (70 per cent) were initially managed conservatively. Appropriate local care and nutrition were provided in all cases. Enteral nutrition was the exclusive nutritional support in 285 patients (85 per cent). In 92 cases with proximal fistulae, methods limiting the fistula output or allowing reinfusion of chyme were required. The overall mortality rate was 34 per cent: 100 per cent in the non-intervention group, 55 per cent after emergency surgery, and 19 per cent after conservative treatment. In the latter group, spontaneous closure was obtained in 88 patients (38 per cent). Overall mortality rate was reduced to 19 per cent in patients treated since 1980. Enteral nutrition with appropriate local care may be used in the majority of high-output enterocutaneous fistulae, with an acceptable rate of spontaneous closure. Conservative management is the treatment of choice in the initial period. Emergency surgery should be restricted to the treatment of haemorrhage or intra-abdominal abscesses associated with uncontrolled systemic sepsis.

Keywords: Small intestinal fistulae, enteral feeding

Modern principles for the management of enterocutaneous fistulae have been formulated over the last 25 years[1–12]. In most reports, the standard technique for the provision of artificial nutrition for these patients is total parenteral nutrition (TPN)[4–8,11–14]. Most authors feel that enteral nutrition with chemically defined diets has only a limited role, and its use is often limited to low-output fistulae[6,15–18].

In the Surgical Digestive Intensive Care Unit of Hôpital Saint Antoine, a referral centre receiving patients from France and other countries, considerable experience in the management of external fistulae has been accumulated. Original techniques to provide enteral nutrition and control fistula output have been developed, allowing the majority of patients to be managed with exclusive enteral support.

The aim of this retrospective study is to describe these techniques and to evaluate the results obtained in patients with high-output external fistulae originating in the small intestine.

Patients and methods

All patients with a postoperative high-output external fistula of the small bowel managed at Hôpital Saint Antoine during the period 1970–86 are presented. 'High-output' is defined as a daily discharge of over 600 ml. There were 335 patients, 198 men and 137 women, of mean age 49·8 years (range 8–85), 82 per cent of patients were referred from other institutions, while 18 per cent were initially operated on at our institution, representing 0·2 per cent of the cases undergoing elective abdominal surgery for the same period.

The primary diagnoses are detailed in *Table 1.* Operations leading to the fistula were performed as an emergency procedure in 40 per cent of cases, and in 17 per cent of patients the indication for operation was a generalized peritonitis. The number of laparotomies before fistula formation ranged from one to six, 72 per cent of the patients having undergone at least two laparotomies. The fistula originated in the jejunum in 117 cases (35 per cent), and the ileum in 218 (65 per cent). The number of openings on the small bowel could be determined in 331 patients. There was a single fistula in 215 patients (65 per cent), two in 69 (21 per cent), and three or more in 47 (14 per cent). A combined urinary fistula was present in 18 cases (5 per cent). The fistula

output ranged from 600 to 6000 ml/24 h, with a median value of 1350 ml/24 h.

When the fistula opening was associated with an abdominal wound dehiscence (165 cases, 49 per cent), it was called an 'exposed fistula'[9]. These were divided into two categories according to their mechanism of formation.

1. *Bowel-to-wall* fistulae (127 cases) were secondary to a leak from the small intestine leading to peritonitis which had drained spontaneously (in the absence of reoperation) through a dehisced incision.
2. *Wall-to-bowel* fistulae were secondary to external trauma inflicted on a superficial loop exposed in an evisceration (38 cases).

Fistulae were called 'direct' when the internal opening was visible from the exterior and situated at the level of or close to the external opening (96 cases, 29 per cent). They were termed 'indirect' when the internal opening was not visible and was separated from the external opening by an intermediary track (239 cases, 71 per cent) The origin of the fistula was a disrupted anastomosis in 161 cases (48 per cent), a necrotic lesion in 42 cases (12 per cent) and a traumatic injury in 111 cases (33 per cent), while no precise cause could be found in 21 cases (6 per cent). The time between the operation preceding the fistula and the development of the fistula itself was evenly distributed between 2 and 15 days in 257 cases; seven fistulae developed earlier and 71 developed later.

Associated conditions

The fistulae were associated with diseased bowel in 84 patients (25 per cent): Crohn's disease in 21 cases, short bowel (residual length less than 150 cm as measured at laparotomy) in 25 cases, and radiation enteropathy in 38 cases.

In an attempt to evaluate the severity of the illness, eight severity factors were considered[9]: multiple fistulae (two or more intestinal openings); intra-abdominal abscess (documented by laparotomy, spontaneous drainage, percutaneous drainage, or post-mortem examination); septicaemia (clinical symptoms and positive blood culture), ileus; adult respiratory distress syndrome (mechanical ventilation required), upper gastrointestinal haemorrhage (more than four units of blood in volume); renal or hepatic failure (serum creatinine >250 μmol/l, serum bilirubin >60 μmol/l, aspartate aminotransferase (ASAT) or alanine aminotransferase (ALAT) greater than three times the upper limit of normal values), thromboembolic complications The incidence of each factor is shown in *Table 2* and the number of severity factors per patient is represented in *Table 3*. In 82 patients (24 per cent) none of these factors was present, and the fistulae in these patients were called 'isolated fistulae'.

Method of management

After initial assessment, one of the three attitudes to treatment was selected: non-intervention, emergency surgery, or medical therapy.

Table 2 *Incidence of severity factors*

Factor	No. of patients	Percentage
Multiple fistulae	116	35
Intra-abdominal abscesses	150	45
Septicaemia	130	39
Ileus	63	19
Adult respiratory distress syndrome	104	31
Upper gastrointestinal tract haemorrhage	60	18
Renal and/or hepatic failure	120	36
Thromboembolic complications	39	12

4	38	11	68
5	35	10	80
6	19	6	76
7+	6	2	
Total	335		

Non-intervention. Before 1978, 21 patients were referred in a moribund state and, despite the urgent need for surgery, were considered to be beyond any possibility of recovery. They received simple supportive therapy and died shortly after admission This approach has not been adopted since 1978 when newer techniques in intensive care became available

Emergency surgery In 80 cases, patients were operated on shortly after admission for the following indications: uncontrolled sepsis, acute haemorrhage or evisceration.

Complete exploration of the peritoneal cavity was carried out in 63 patients and the fistula was exteriorized or defunctioned as a temporary stoma. In 19 of these patients, a special procedure was required to close the midline incision without tension[19] In 13 patients, the abdominal wall was left open.

A limited operation for elective drainage of a septic collection or treatment of acute haemorrhage was carried out in 17 cases and the fistula was not dealt with.

Conservative treatment (234 cases) Together with the usual intensive supportive therapy, the two main pillars of medical treatment were local fistula care and nutritional support

Local fistula care comprised irrigation of the fistula track with aspiration of the fistula contents. Irrigation of the fistula track[2] was routinely undertaken with a fine-bore silicone tube and a solution of 0·45 per cent lactic acid instilled at a mean rate of 2500 ml/24 h. Aspiration of the fistula fluid was achieved with a variety of tubes. The basic system consisted of large-bore silicone tubes provided with an air circulation channel and connected to a vacuum bottle regulated at a negative pressure of 50 mbar. In fistulae without parietal dehiscence and with an intermediary track, the irrigation tube was inserted deeply into the track and the fluid was collected by a tube positioned in the track close to the surface or in a simple karaya-sealed appliance to which strong aspiration was applied In direct fistulae with a small external opening, irrigation was superficial and the fluid was collected in a karaya-sealed appliance. In exposed fistulae, the abdominal wall dehiscence was circumscribed by a karaya dam, the irrigation tube was positioned close to the intestinal opening, and the aspiration tube was securely maintained by a wire frame positioned at its most dependent part.

In 64 patients with lateral fistulae that were proximal and well walled off, an attempt was made to limit the fistula discharge by means of an obturating device such as cellulose sponges with lead loads, karaya paste plugs, or infusion of a 3 per cent karaya solution[9]

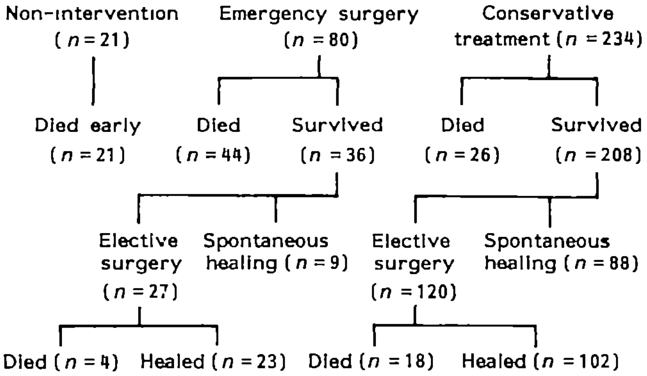
In 28 patients with lateral proximal fistulae everted in an evisceration, the enteric content collected from the proximal end was reinfused into the distal end[20].

Continuous enteral nutrition This was undertaken as soon as possible after admission or reoperation, and was the exclusive method of nutritional support in 285 patients (85 per cent). Among these patients, TPN was required for a period exceeding 5 days in 71 cases, the mean duration of TPN before conversion to enteral support being 17 days

TPN was the method of nutritional support used in 50 patients, 46 died early after referral and before any attempt at changing to enteral nutrition was possible, while the remaining four patients had less than 80 cm of small bowel remaining.

The diet routinely used for enteral support included glucose polymers, protein hydrolysates, medium chain triglycerides and essential fatty acids. A viscous additive (Amidon-Visco®, Gallia Laboratories, F 92203 Levallois, France) produced a 200-fold increase in the viscosity of the diet, thus slowing intestinal transit and allow absorption of the nutrients from the first 150 cm of small intestine[21] The osmolality of the diet was between 300 and 350 mosm/l, and its caloric concentration was equal to 2·09 kJ/ml at the onset of infusion, reaching 4·18 kJ/ml at full infusion rates. The volume infused and the caloric concentration were gradually increased, and the caloric load after a mean of 10 days reached a plateau of 250·8–459·8 kJ/kg body weight per day. The amount of calories delivered enterally depended on the severity of the sepsis associated with the fistula, as patients with severe sepsis require a higher intake to achieve weight gain[21]. The amount of the enteral intake was also correlated to the fistula output, a higher intake being delivered in high-output fistulae The aim was to achieve a net intake of 209 kJ/kg per day and a positive nitrogen balance of 4–6 g/day

Elective surgery. 120 patients in the group of 234 receiving conservative treatment underwent elective surgery, together with 27 patients who survived emergency surgery and in whom the fistula had been exteriorized as a stoma. Surgical repair of the fistula was carried out after a minimal period of 60 days from the previous operation



Non-intervention (n = 21)
Emergency surgery (n = 80)
Conservative treatment (n = 234)
Died early (n = 21)
Died (n = 44)
Survived (n = 36)

Figure 1 *Outcome of the patients*

Basically the segment of bowel bearing the fistula was excised and the ends were anastomosed but, in the presence of multiple openings into the intestine, lateral suture after excision of scar tissue was preferred.

Results

Therapeutic pathways and mortality

The outcome in the 335 patients is shown in *Figure 1*. The 21 patients in the non-intervention group died shortly after admission. Of the 80 patients undergoing emergency surgery, 44 died early (55 per cent), 27 came to elective surgery (34 per cent) with four deaths, and in nine patients spontaneous closure occurred (11 per cent). In the group of 234 patients managed conservatively, 26 died during the course of supportive therapy (11 per cent). In 120 patients the fistula failed to close and they came to elective surgery (51 per cent); 18 of these patients died. Spontaneous fistula closure occurred in 88 of the patients treated conservatively (38 per cent).

The overall mortality rate was 34 per cent (113 of 335). Survivors remained in hospital for a mean period of 72 days, and a mean of 43 days were spent in the intensive care unit.

Factors influencing survival

Age. The mortality rate was 20–25 per cent in patients below the age of 50 years, rose to 35 per cent in the fifth decade, and reached 45 per cent in older patients.

Time. The mortality rate was 43 per cent before 1980 (209 patients), and 19 per cent after this date (126 patients)

Characteristics of the fistula. Exposed fistulae were associated with a mortality rate of 44 per cent as opposed to 23 per cent in those that were not associated with evisceration ($P < 0{\cdot}001$). Fistula output over 1500 ml significantly increased the mortality rate (39 *versus* 28 per cent, $P < 0{\cdot}05$). Jejunal fistulae carried a higher, but not significantly higher, mortality rate than ileal fistulae (39 *versus* 31 per cent, $P < 0{\cdot}1$). Late development of the fistula (>15 days after surgery) was associated with a slightly better prognosis (25 per cent mortality rate *versus* 36 per cent in earlier cases, $P < 0{\cdot}1$).

Severity factors. Each severity factor significantly affected the prognosis (all $P < 0{\cdot}01$, *Table 4*). The cumulative number of severity factors per patient was closely correlated with mortality rate (*Table 3*). In the absence of severity factors, the mortality rate was only 4 per cent.

Factors influencing spontaneous healing

Among the 234 patients initially managed with conservative treatment, there were 106 exposed fistulae of which 24 closed spontaneously (23 per cent), and 128 fistulae without parietal dehiscence of which 64 healed spontaneously (50 per cent). In the group of wall-to-bowel exposed fistulae, only four of a total of 30 fistulae treated conservatively healed spontaneously (13 per cent).

Patients in whom non-surgical closure of the fistula was achieved were referred at a median time of 9 days after onset of the fistula; the fistula healed after a mean period of medical treatment of 27 days and the total length of time the fistula was present was 39 days (median value). Patients requiring elective surgery were referred at a median time of 26 days after fistula onset, surgical repair was undertaken at a mean of 51 days after admission, and the total length of time the fistula was present was 83 days (median value).

Discussion

TPN has gained wide acceptance in the management of enterocutaneous fistulae. It has also been suggested that bowel rest might favour spontaneous healing[13]. This hypothesis was challenged when reports showed that enteral feeding with elemental diets was also associated with an absence of stimulation of gastrointestinal secretions[18,22], and with a decrease of fistula output similar to that obtained by TPN[16]. Reber *et al.*[6], reporting the results of fistula management with both TPN and elemental diets, showed that equivalent results were obtained in terms of mortality rate and spontaneous closure. Bowel rest and TPN are undoubtedly helpful in terms of nutritional support, fluid and electrolyte control and local care, but it is now widely agreed that healing of the fistula is primarily related to the local anatomical conditions[12,23].

Continuous enteral nutrition has been used since 1965 by our group as a method of nutritional support in the management of enterocutaneous fistulae[21]. It was initially feared that a marked increase in fistula output might occur, but this proved to be the case only in patients with high jejunal fistulae, and that problem has been solved by fistula obturation or reinfusion of chyme The results in the present series attest the validity of this method of nutritional support, as almost all patients could be managed by exclusive enteral alimentation after only a short period of TPN. However, there may be another objection to this mode of nutrition in that polymeric formulae stimulate gastrointestinal secretions and increase both the volume and the enzyme concentration of the fistula fluid. This may result in difficulty in local care and prevent spontaneous healing In fact, these potential drawbacks may be offset by the irrigation of the fistula track, which neutralizes the deleterious effect of the enzyme-rich fistula fluid, and by obturating systems, which obstruct the fistula discharge and provide a favourable environment for tissue granulation and healing.

In the present series, spontaneous healing of the fistula was obtained in 88 of the 234 patients (38 per cent) initially managed with conservative treatment, and spontaneous closure was still seen in 23 per cent of patients with exposed fistulae despite abdominal wall dehiscence These figures are comparable with the results obtained with TPN in recent series, where the rate of fistula healing ranges from 19 to 49 per cent[6,7,12,23–25]. Higher rates of spontaneous healing have been reported from other institutions[4,13,26,27], but comparison between series should be made with care, as the characteristics of the fistulae may differ markedly from one institution to another. Some

Table 4 *Relationship between severity factors and prognosis*

Severity factor	Mortality rate when factor present (%)	Mortality rate when factor absent (%)
Multiple fistulae	48	26
Intra-abdominal abscesses	51	20
Septicaemia	55	20
Ileus	62	27
Adult respiratory distress syndrome	69	18
Upper gastrointestinal tract haemorrhage	62	28
Renal and/or hepatic failure	66	16
Thromboembolic complications	64	30

referral centres deal with a major proportion of complicated cases referred after failure of previous therapy in the initial institution and therefore report a high rate of surgical closure.

With continuous enteral nutrition the prolonged use of intracaval catheters can be avoided. While TPN-related septic complications have reached a low incidence in specialized nutritional units dealing with patients in an acceptable general condition[12,28], they remain a major threat in patients with organ system failure and septic abdominal complications managed in an intensive care unit[24].

Non-intervention in patients thought to be too severely ill to sustain emergency surgery is an approach that we have not adopted in our institution since 1978. Emergency surgery carries a high risk of mortality, and the indications have therefore changed throughout the study period. In the early 1970s, a larger proportion of patients were reoperated on shortly after admission if there was suspicion of intra-abdominal sepsis as we felt that surgical exploration was necessary in such patients referred after multiple operations, in order to evaluate precisely the intraperitoneal lesions. We have now restricted the indications for urgent surgery to major haemorrhage or uncontrolled septic complications.

Conservative therapy is now the treatment of choice in the initial period, the cases considered for late elective surgery being those in which the fistula is not healed after 6 weeks of appropriate management and those where local conditions preclude spontaneous closure (i.e. exposed fistulae with the intestinal mucosa lying in continuity with the surface of the granulation tissue, terminal fistulae and those cases with distal obstruction).

Elective surgery should be undertaken at least 6 weeks after resolution of the signs of intra-abdominal sepsis, this often corresponding to 60–75 days after the initial surgery[10,12,23,29,30]. In the group of patients with exposed fistulae, those due to trauma after evisceration (wall-to-bowel fistulae) may be operated on early after their formation if they occur a long time after the initial surgery.

It should be pointed out that, in our series, patients referred a long time after the onset of their fistula had a lower rate of spontaneous closure than those who were admitted earlier. The reasons for this are probably twofold: firstly, a prolonged period of inappropriate therapy may allow the development of a fibrous and well organized track; secondly, there is a bias in the above comparison as the cases referred relatively late are those where conservative management has already proved unsuccessful.

In conclusion, the mortality rate for high-output enterocutaneous fistulae remains high at around 20 per cent[23,28] despite progress in intensive care and nutritional support. This lack of improvement has already been pointed out[6,7] and is probably related to the increased severity of illness in the patients referred to specialized centres. While simple cases may be managed successfully in the original institution, complex enterocutaneous fistulae should be referred promptly to specialized units[31] where optimal conditions for local management and artificial nutrition are combined. Continuous enteral nutrition associated with special techniques of local care has proved a viable method of support in patients with high-output small bowel external fistulae.

Acknowledgements

The authors are grateful to Professor Graham L. Hill (Auckland, New Zealand) for reviewing the manuscript and making many valuable suggestions. They also thank Mr M. A. Quilichini for reviewing the data and Mrs M. Esnault for helpful assistance in preparation of the manuscript.

Minimally invasive surgery for the retrieval of complex fractured double J stents

C. R. Chapple, J. Gelister and R. A. Miller

Department of Minimally Invasive Surgery, The Institute of Urology, Shaftesbury Avenue, London WC2, UK

Correspondence to: Mr C. R. Chapple, Department of Urology, Middlesex Hospital, London W1, UK

The increasing use of ureteral endoprostheses over the last 10 years has resulted in the documentation of a number of complications, namely occlusion, migration, perforation, fistulae, stone encrustation and spontaneous fracture. This last situation can result in serious consequences, as disintegration of a stent results in the deposition of multiple friable stent fragments in an already compromised upper urinary tract. We report a patient who had a double J stent inserted to traverse a malignant stricture of the lower third of the ureter and who was referred to our unit with stent fracture.

Case report

A 67-year-old man was diagnosed 6 years previously as having a T_3 adenocarcinoma of the prostate. His right kidney had been removed in the past for stone-related disease. Despite appropriate therapy he presented 2 years later in renal failure with a malignant obstruction of the left vesicoureteric junction. A double J stent was inserted. At the time of referral to our unit he was suffering from recurrent severe urinary tract infections associated with multiple stent fragments in the lower part of the left ureter. Transurethral cystoscopy was difficult because of malignant infiltration of the prostatic urethra resulting in a rigid prostatic fossa. Suprapubic cystoscopy was therefore necessary via a percutaneous track[1]. A direct transabdominal puncture of the left ureter on to the radio-opaque fragments was performed (*Figure 1*). Methylene blue was injected through the needle directly into the ureter, allowing the left ureteric orifice to be visualized. Suprapubic endoscopic urethrotomy of the intramural ureter was then possible allowing instrumentation via the percutaneous cystotomy. The left renal pelvis was opacified allowing a percutaneous nephrostomy tract to be established. Stent fragments were then removed under direct vision using percutaneous antegrade ureteroscopy via the nephrostomy tube with a Fogarty balloon catheter (*Figure 2*).

A good clearance of the left renal tract was accomplished with a few residual fragments remaining in the urothelium. The patient developed no complications after this treatment and has had no further urinary tract infections.

Discussion

The use of straight stents inserted endoscopically into the ureter was first described by Zimskind *et al.* in 1967[2]. A major advance in stents was heralded with the development of the double J stent, the pigtails at either end securing the stent in the kidney and bladder and preventing its migration[3]. No therapeutic advances, however, are without complications.

Although designed for use as temporary prostheses a number of double J stents have been left *in situ* for long periods. It has become apparent that after a sojourn in excess of 6 months[2], these stents are increasingly prone to fracture, although silicone or polyurethane stents are less prone to breakage than polyethylene ones[3]. Fracture of double J stents results in a multitude of fragile fragments within the upper urinary tract, which then result in obstruction and renal colic and may be the focus for persistent urinary tract infections, as shown here.

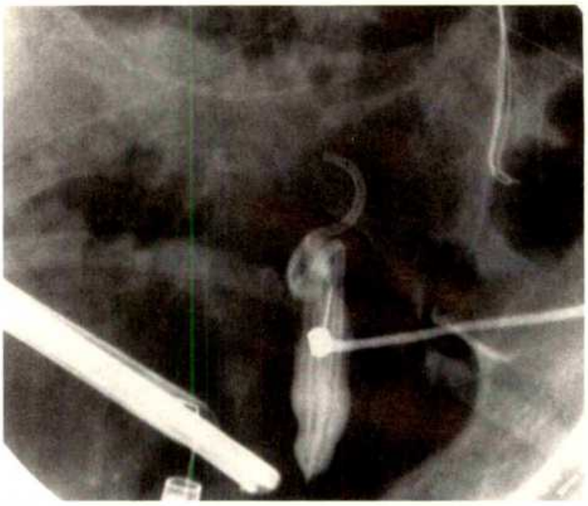

Figure 1 *Direct needle puncture of ureter with opacification. Suprapubic and vesical endoscopies* in situ

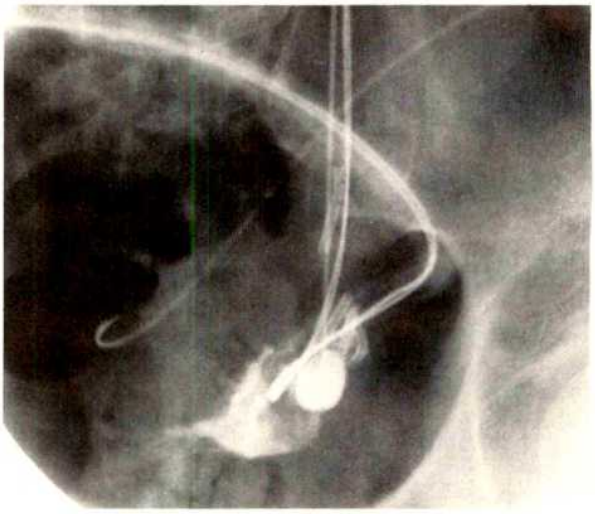

Figure 2 *Retrieval of stent particles with Fogarty catheter*

The retrieval of such a situation presents the endoscopic surgeon with a difficult technical challenge requiring a variety of endoscopic and radiological techniques and expertise. The case reported here demonstrates this and emphasizes the usefulness of the Fogarty balloon catheter technique as the fragility of the stent material precludes the use of biopsy forceps or mechanical snares.

Colon interposition in children

Since 1960 we have performed 80 colonic interpositions on 79 children. We present a retrospective review of their progress. Sixty-nine interpositions were for long-gap oesophageal atresia, while the remainder followed oesophagectomies, eight for strictures and two others. Overall, the transthoracic route was used in 69 per cent of cases, while 29 per cent were retrosternally placed and one was retropleural. The mean follow-up was 11·08 years. The mortality rate was 12 per cent, with one-third of deaths unrelated to the operation. Graft failure, which occurred on eight occasions (10 per cent), was due to ischaemia in four, intractable stricture in two and stomal ulceration in two. Leakage from the proximal anastomosis occurred in 31 per cent of cases and stricture formation in 27 per cent. Thirty per cent of patients complained of acid reflux, of whom one-third developed stomal ulceration. We present data concerning other complications, including long-term recurrent respiratory infections, malabsorption, gastrointestinal haemorrhage, diarrhoea, intestinal obstruction and redundancy of the graft. Staging the procedure did not affect the outcome, however the higher incidence of serious complications encountered following retrosternal interposition finally led us to abandon this procedure in favour of the transthoracic route. There has been little improvement in the growth rate, but in terms of swallowing ability the outcome was satisfactory in 94 per cent of cases.

The origins of oesophageal replacement surgery lie with Bircher[1], who in 1907 described a technique for bypassing the oesophagus with an antethoracic skin tube. In 1907 Roux[2] performed the first antethoracic jejunal interposition, and in 1911 Kelling[3] performed the first antethoracic colonic interposition. It was not until 1948, however, that the first intrathoracic colon interposition was described[4]. Since then two techniques have been popularized, that described by Javid[5] in 1954 using a retrosternal route, and that described by Waterston[6] in the same year using a route through the diaphragm, the left chest and the apex of the left pleura. A modification of the latter technique, placing the colon extrapleurally in the normal oesophageal site, after passing through the oesophageal hiatus, was put forward by Freeman and Cass in 1982[7] and reviewed in 1986[8].

From 1960 to 1987, 80 colonic interpositions have been performed on 79 children at the Birmingham Children's Hospital, together with three jejunal interpositions. We present our results and analyse the outcome after prolonged follow-up.

Patients and methods

The indications for colonic replacement of the oesophagus in children are summarized in *Table 1*, but in the vast majority (69) of the 79 cases, long-gap oesophageal atresia was the cause. Exploratory thoracotomy was performed in all cases presenting with a tracheo-oesophageal fistula in addition to oesophageal atresia and in eight cases primary anastomosis was attempted but failed. In children with pure oesophageal atresia, however, exploration was rarely attempted as primary anastomosis is unlikely to be possible owing to a short distal pouch in this group of patients.

Eight interpositions were performed for severe oesophageal strictures which could not be adequately dilated, one followed resection of a benign oesophageal tumour and one was in a patient who had had a successful primary anastomosis for oesophageal atresia but who had an atonic oesophagus and severe reflux, without stricture.

During the same 27-year study period, 432 cases of oesophageal atresia were referred to the Department of Cardiothoracic Surgery at the Birmingham Children's Hospital, giving an overall 'interposition rate' of 16 per cent. This is in keeping with results from other centres: Southampton 25 per cent[8], Iowa 9 per cent[9]. All but three colon interpositions were performed by one of two surgeons (K. D. R. and L. D. A.).

The mean ages of patients at operation for each of the three groups are summarized in *Table 2*.

Of the 79 patients undergoing colonic interpositions, records and follow-up were insufficient in only three. Of the remaining 76 patients, the average follow-up was 11 years and 1 month with a range of 21 days (patient died) to 27 years. In almost all children one or more barium swallows were performed during the follow-up period using both a liquid contrast medium and a solid one (barium soaked marshmallows).

Out of 67 children with oesophageal atresia 25 (37 per cent) had a total of 53 other congenital abnormalities.

Table 1 *Indications for colonic replacement of the oesophagus in children*

	No. of cases
Oesophageal atresia ($n=69$)	
Large gap (36 Type A, 25 Type D)	61
Failed primary anastomosis (8 Type A)	8
Oesophageal stricture ($n=8$)	
Failed anti reflux procedure with repeated dilatations	
Reflux stricture	1
Caustic stricture or congenital stenosis	0
Intractable stricture	
Reflux stricture	7
Caustic stricture or congenital stenosis	0
Other ($n=2$)	
Oesophageal leiomyoma	1
Atonic oesophagus with reflux	1

Table 2 *Age at operation*

	Mean age (years)	Range (years)
Atresia group	0·9	0·5–2·0
Stricture group	7·0	0·4–15·8
Others	12·3	12·1–12·5

All patients in the atresia group underwent oesophagostomy and gastrostomy before the colon interposition. In 12 per cent of cases the distal oesophagus was absent. Bowel preparation was carried out in all cases and consisted of a low residue feed combined with rectal washouts on the day before surgery. One interposition was performed through a median sternotomy incision, while the remainder were performed through left thoracoabdominal and left cervical incisions (69 per cent), or transverse abdominal and left cervical incisions (29 per cent). Interposition in the atresia group was performed as a single stage procedure in 28 per cent of cases, and as a two stage procedure (initially creating a cervical colostomy with delayed proximal anastomosis) in 72 per cent of cases In the stricture and miscellaneous groups, in all but one case an oesophagectomy was performed at the same time as colonic replacement (itself performed in one stage) All these operations were carried out via a left thoracoabdominal approach.

Overall, transverse colon was used in 79 per cent of cases and ascending colon in the remainder The blood supply was based on the left colic artery in 88 per cent of patients, the middle colic in 11 per cent and on the right colic in one patient All nine interpositions in the stricture and miscellaneous groups involved transthoracic replacement of the oesophagus In the atresia group, however, two grafts became ischaemic even before anastomosis but, of the remaining 66 grafts carried out in 65 patients, 43 (65 per cent) were of the transthoracic (Waterston) type, 22 (33 per cent) were retrosternal and one was retropleural (as described by Freeman and Cass[7]) All grafts were anastomosed to the cervical oesophagus, except for seven of the nine patients in the stricture and miscellaneous groups in whom anastomosis was to the thoracic oesophagus. All grafts were isoperistaltic. Distal anastomosis was to the stomach where the retrosternal route was used, but with the Waterston technique anastomosis was to the distal oesophagus, with the colon's vascular pedicle passed up through a separate (new) hiatus in the left diaphragm. Only where the oesophagus was excised or where a distal segment was absent was the colon and its pedicle passed up through the true 'oesophageal' hiatus.

In two patients, both of whom had had oesophagectomies, a pyloroplasty was performed at the time of colonic interposition In only one other case was a pyloroplasty performed subsequently, but this was in a patient with a retrosternal graft and stomal ulceration who had had an antireflux fundoplication.

A nasogastric or Replogle tube was left in position after proximal colo-oesophageal anastomosis in 47 per cent of cases and an intercostal chest drain was used following a thoracoabdominal approach; it was, however, removed within the first three postoperative days in 82 per cent of patients.

Results

Mortality

Of the 76 patients for whom records and follow-up are adequate, there were nine deaths (12 per cent), seven from the atresia group (10 per cent), one from the stricture group and one following oesohagectomy for a leiomyoma. One death in the early postoperative period was due to multisystem failure following septicaemia from severe respiratory infection after a two-stage transthoracic interposition.

Five deaths were late but related to surgery; one was due to a pulmonary embolus 6 years after the original (two stage retropleural) interposition, but 2 weeks after revision of the distal anastomosis for redundancy. Of the remaining four deaths, one was due to septicaemia and three to respiratory failure after aspiration. Three of these followed a transthoracic interposition and one a retrosternal interposition, two performed in one stage and two in two stages. There were three late unrelated deaths: one due to a cerebrovascular accident, one to influenza and one to an asthmatic attack. These last two patients had had previous failed grafts.

Graft failure

Failure of the colonic interpositions occurred eight times (10 per cent) in seven patients (9 per cent), all of whom were from the atresia group. In two patients the prepared colon graft was found to be ischaemic before anastomosis; in one of these patients a gastric interposition was used instead and in the other a jejunal interposition: both patients have had a successful outcome

Of the five remaining patients, three initially had retrosternal grafts. One was replaced by a transthoracic jejunal graft after failure of the colonic interposition at 4 years due to perforation and bleeding of a stomal ulcer. The second had a gastric interposition for graft failure at 4 years after the development of an intractable stricture. The third patient developed a chronic stomal ulcer which repeatedly bled necessitating graft resection at 9 years. A jejunal graft became ischaemic while the patient was still in the operating theatre and therefore a stomach tube was created from the lesser curve. This too became necrotic after 1 week and was replaced with a jejunal graft supplied in part (distally) by its own vascular pedicle, but with a microvascular anastomosis proximally to the innominate artery and left internal mammary vein.

Two other patients had failed grafts, both after transthoracic interpositions: one was due to an intractable stricture, replaced after 3 years by a gastric interposition, and one was due to necrosis of the graft at 10 days due to ischaemia. In this patient a second graft was fashioned, this time from the right colon, and placed retrosternally, but this also became necrotic at 1 week.

These results are summarized in *Figure 1*. There was no difference in the graft failure rate whether interposition was performed in one or two stages.

Anastomotic complications

Of the 75 viable colonic interpositions, proximal leakage was the commonest anastomotic complication, occurring on 23 occasions (31 per cent), 14 after transthoracic interpositions (27 per cent) and nine after retrosternal interposition (41 per cent). Although leakage occurred more often after retrosternal interposition, this difference was not significant ($\chi_1^2 = 1{\cdot}41$, $P > 0{\cdot}1$). Sixteen were treated conservatively, but seven required revision of the anastomosis. Leakage from the distal anastomosis occurred in only one case. This followed a transthoracic interposition and resolved with conservative treatment.

Stricture formation occurred at the proximal anastomosis on 17 occasions (23 per cent) with a significant difference between transthoracic (eight patients, 15 per cent) and retrosternal (nine patients, 41 per cent) interpositions, ($\chi_1^2 = 5{\cdot}71$, $P > 0{\cdot}02$). One patient developed a distal stricture after a transthoracic interposition and two patients who had had retrosternal grafts developed both upper and lower strictures, as did one patient after a transthoracic interposition.

In only five patients did stricture formation follow an anastomotic leak, but in one such patient, investigated for recurrent respiratory infections 2 months after surgery, a fistula was found between the colo-oesophageal anastomosis and the trachea. This and the stricture were resected, but the stricture recurred and required further resection followed by repeated retrograde dilatations.

In two cases stricture formation eventually resulted in graft failure, but in the remainder operative intervention produced a satisfactory outcome: five required dilatation (antegrade or retrograde) only, and ten required revision of the anastomosis. However, six of these required a further revision of which two required a third revision.

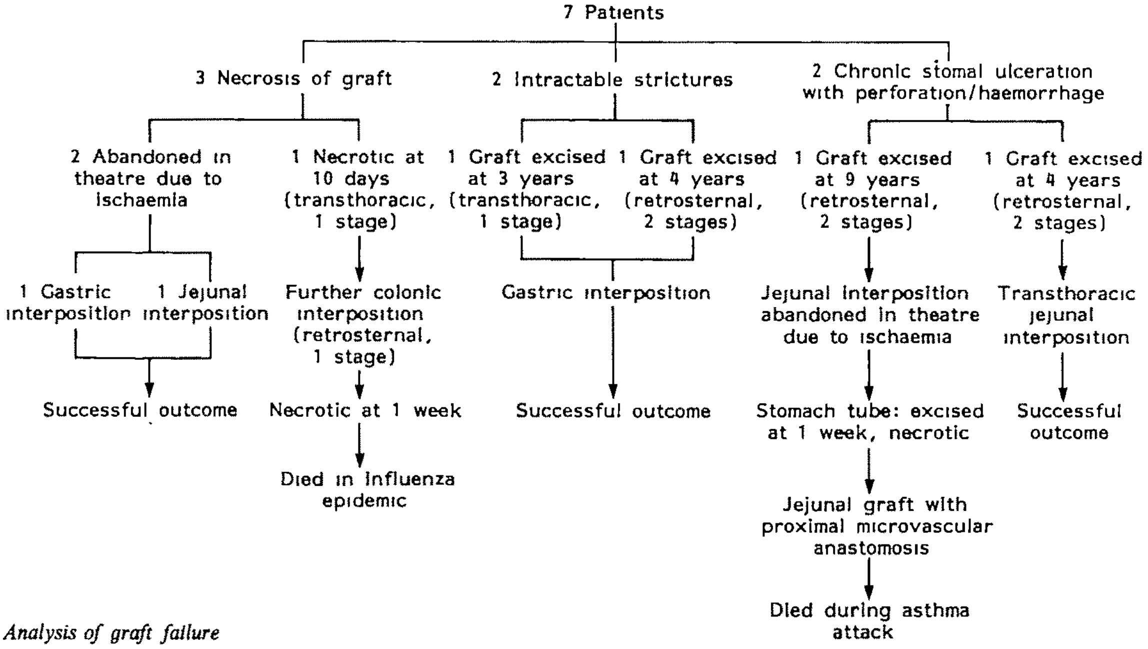
From *Table 3* it can be seen that staging the procedure did not significantly alter the incidence of anastomotic leakage or stricture formation, ($\chi_1^2 = 2{\cdot}44$, $P > 0{\cdot}1$).

In only one patient was there an anastomotic complication related to the colocolostomy. This was a minor leakage which was treated conservatively.

Table 3 *Analysis of anastomotic complications*

Stage	No of interpositions	No. with anastomotic leakage stricture, or both	Anastomotic leakage		Anastomotic stricture		
			Proximal	Distal	Proximal	Distal	Both
1	26 (35)	10 (38)	5 (19)	1	3 (12)	1	2
2	49 (65)	26 (53)	18 (37)	0	11 (22)	0	1
Total	75	36	23	1	14	1	3

Values in parentheses are percentages



7 Patients
3 Necrosis of graft
2 Intractable strictures
2 Chronic stomal ulceration with perforation/haemorrhage
2 Abandoned in theatre due to ischaemia
1 Necrotic at 10 days (transthoracic, 1 stage)
1 Graft excised at 3 years (transthoracic, 1 stage)
1 Graft excised at 4 years (retrosternal, 2 stages)
1 Graft excised at 9 years (retrosternal, 2 stages)
1 Graft excised at 4 years (retrosternal, 2 stages)
1 Gastric interposition
1 Jejunal interposition
Further colonic interposition (retrosternal, 1 stage)
Gastric interposition
Jejunal interposition abandoned in theatre due to ischaemia
Transthoracic jejunal interposition
Successful outcome
Necrotic at 1 week
Successful outcome
Stomach tube: excised at 1 week, necrotic
Successful outcome
Died in influenza epidemic
Jejunal graft with proximal microvascular anastomosis
Died during asthma attack

Figure 1 *Analysis of graft failure*

All anastomotic strictures occurred in the atresia group, as did all but two cases of leakage, both proximal.

Long-term complications

The most important long-term complication encountered, which finally led to the abandoning of the retrosternal method of interposition in our unit, was the occurrence of acid reflux into the colon graft, leading to ulceration and in many cases to haemorrhage

Six of the 76 patients studied either died too soon after surgery or were lost to follow-up too soon to be included in an analysis of long-term complications. However, in the remaining 70 (50 transthoracic, 20 retrosternal) a total of 21 (30 per cent) patients complained of acid reflux (nine transthoracic, 12 retrosternal), i e 18 per cent of patients with transthoracic interposition developed reflux compared with 60 per cent patients with a retrosternal graft. All but three patients were from the atresia group. Five patients (all retrosternal) required operative intervention as detailed below, but the remainder have been successfully treated with conservative measures

Frank ulceration of the colon graft occurred in seven cases, all with retrosternal interpositions; two of these went on to perforate and bleed, leading to graft failure. One patient who developed an ulcer was treated adequately with medical therapy and one required ulcer excision and fundoplication Three patients developed ulcer-related haemorrhage, two requiring surgery. One of these patients also had colitis and fat malabsorption and subsequently developed melaena which responded to Salazopyrin® (Pharmacia G.B. Ltd., Milton Keynes, UK) therapy These results are summarized in *Figure 2*

In all, gastrointestinal bleeding occurred in nine patients (13 per cent), three transthoracic and six retrosternal. In five patients the haemorrhage was ulcer-related as described above: in two (one retrosternal, one transthoracic) the cause was unknown, in one it was due to mild inflammation of the colon graft, and in one it was due to gastritis, these last two patients and one whose cause was unknown were from the stricture and miscellaneous groups and the remainder were from the atresia group Only four, all ulcer-related, required surgery

The commonest complication encountered was recurrent respiratory infection due to presumed aspiration (although many of these children were asthmatics). This was encountered in 25 children (36 per cent), 17 with transthoracic and eight with retrosternal grafts, i.e. 34 per cent of children with transthoracic grafts complained of recurrent respiratory infections compared with 40 per cent with retrosternal grafts. It is interesting to note that the problem disappeared in one child with a retrosternal graft after having an antireflux procedure performed

Diarrhoea was a feature in 19 children (27 per cent), 12 transthoracic and seven retrosternal, i.e. 24 per cent of those with a transthoracic graft and 35 per cent of those with a retrosternal graft. Two patients also developed malabsorption, one due to colitis

Intestinal obstruction was encountered in 14 cases (20 per cent). Twelve were due to adhesions, six of which required laparotomy Two cases were due to internal hernias, one through the diaphragm and one through the transverse mesocolon.

Anaemia developed in seven patients (10 per cent) In one it followed transthoracic interposition and was due to renal failure and in the remainder it followed retrosternal interposition and was due to gastrointestinal bleeding (four) or unknown causes (two). Halitosis was reported in nine children, seven after transthoracic interpositions Redundancy of the colonic graft occurred in four cases (6 per cent, three transthoracic). Three required no specific treatment, but one required side-to-side cologastrostomy (transthoracic graft). Wound dehiscence occurred in three cases (4 per cent) all after transthoracic interposition via a thoracoabdominal incision. A permanent

Retrosternal	—	—	—	—	—

left recurrent laryngeal nerve palsy occurred in three patients (4 per cent) postoperatively, all after transthoracic interposition and one patient (transthoracic) developed a left phrenic nerve palsy.

Although other complications, such as dumping and Horner's syndrome have been reported[10,11], no such complications were apparent in our series. Despite a 20-year follow-up in some patients, diverticulosis and carcinoma of the colon graft have not been observed so far.

Outcome

Excluding patients who died, required second grafts, had inadequate records, were lost to follow-up or had follow-up of less than 1 year, there remained 56 with a successful colonic interposition in whom we were able to assess the long-term outcome and 51 in whom we were able to follow the pattern of growth and development (mean follow-up 14·0 years, range 2·4–26 years).

The outcome in terms of dysphagia was classified as follows, according to the criteria adopted by Ahmed and Spitz[12]: excellent, asymptomatic, normal diet; good, predominantly asymptomatic, but occasional dysphagia; and fair, significant dysphagia with or without repeated dilatations.

Only three patients (5 per cent) reported anything less than a good or excellent result, however, those who had had a retrosternal graft were less likely to be completely free of dysphagia than those who had had a transthoracic interposition. In the atresia group 50 per cent of transthoracic patients had an excellent result compared with 15 per cent of retrosternal patients. However, virtually all patients were able to eat a normal diet (*Table 4*)

Analysis of growth curves revealed that 75 per cent of patients in the atresia group who required colonic interposition had a birthweight at or below the 25th percentile but that, overall, the trend as growth occurred was to remain below the 25th percentile for weight and height: at follow-up 85 per cent were below the 25th percentile for weight and 67 per cent were below the 25th percentile for height.

Records and follow-up for patients surviving in the stricture group are adequate in only two cases, but it is interesting that both of these patients underwent substantial growth spurts from below the 50th to above the 75th percentile.

Discussion

The commonest indication for oesophageal reconstruction in children is long-gap (greater than 6 cm) oesophageal atresia. If primary anastomosis is impossible, delayed primary anastomosis may be attempted after a period of elongation of both the proximal and distal pouches by a variety of methods of bougienage[13,14], possibly supplemented by a circular myotomy of the upper segment[15]. If this fails to produce adequate length, some form of interposition is required. The simplest form of oesophageal replacement in these children, and for others who have undergone oesohagectomy for strictures, tumours or other reasons, is total gastric transposition with intrathoracic oesophagogastrostomy. This approach was once unpopular owing to the high incidence of reflux, oesophagitis, stricture formation and nutritional and growth problems that occurred in children. However, recent results reported by Spitz[16] are more encouraging.

A reversed gastric tube constructed from the greater curve of the stomach has been used with some success[17–20], but it necessitates a long suture line which is prone to leakage. Reflux of acid leading to oesophagitis is also a problem, and in infants an intrathoracic stomach, whether present as a tube or in its normal state, represents a large volume which, especially when distended with air, can severely compromise lung function.

Jejunal interposition has been used with some success[21] and has the advantage of being a conduit of appropriate size which retains vigorous peristalsis. However, the vascular pedicle is invariably short and restricts the length of jejunum that can be used. In children especially, the blood supply is even more precarious and rarely is it possible to achieve a proximal anastomosis above the level of the aortic arch. In our series three jejunal grafts were fashioned after failure of colonic interposition. In one of these patients the graft was abandoned at operation because of ischaemia, but the other two have had a satisfactory long-term result and neither has developed alkaline oesophagitis.

Improvements in microvascular techniques have led to the use of free jejunal grafts. Initial experience involved drawing up a loop of jejunum into the neck based on a mesenteric vascular pedicle, but augmenting the blood supply by anastomosis of a part of the vascular arcade to the internal mammary vessels in the upper part of the chest. This technique was described by Longmire[22] and a modification was used by us in one patient with atresia aged 17 years who had previously had multiple graft failures; venous anastomosis was to the internal mammary vein and arterial anastomosis via a saphenous vein conduit, to the innominate artery. The outcome from this was successful with a good functioning graft, but unfortunately the patient died 7 months later from unrelated causes.

More recently experience in the use of totally free jejunal grafts has been gained in several centres, notably Emory University (Atlanta, Georgia, USA). Jurkiewicz[23] reports only a 10 per cent graft failure rate in 55 patients which compares favourably with any other method available. However, this procedure requires a degree of technical skill that would limit its use to only a few centres. Furthermore, the patients reported in this series were all adults. However, the application of this technique to children remains much less clear because of the small size of the vessels concerned.

In 1986 Halsband[24] reported a further method of interposition using a free autologus jejunal mucosal conduit. Based on the observation that after Livaditis myotomy[15] there remains only a mucosal/submucosal tube bridging the gap, with secondary coating by fibrous tissue and, after Rehbein's olive and thread method[14], a channel is created from mediastinal granulation tissue with secondary oesophageal mucosal lining, H. Halsband, U. Brockmuller and M. Volpel (unpublished results) have tested whether long-gap oesophageal atresia in animals could be bridged by a free transplanted autologous mucosal/submucosal jejunal tube. Provided the grafts were splinted and bougienage was performed during the period of maximal wound contraction, the results after 6 years follow-up were impressive. This technique has now been tried in two neonates and results are again encouraging

Colonic interposition is currently the most popular form of oesophageal replacement in children with a preference for use of the left colon: this is less bulky than the right colon, more used to propelling a solid than a liquid bolus, and does not involve sacrifice of the terminal ileum, with its consequent impairment of vitamin B_{12} absorption[26]. In addition, the left colon has a more favourable blood supply based on the left colic artery which, when the colon is drawn up into the chest, comes to lie in a straight line, with no kinking. However, in our series there were no anastomotic complications in the five patients with a transthoracic interposition using the right colon and in the 12 patients with retrosternal interpositions using the right colon, the incidence of leakage and stricture formation was 58 per cent and 33 per cent respectively, compared with 20 per cent and 50 per cent in the ten patients where left colon was used.

The most popular route for the interposition is that described by Waterston[6] The main alternative is the retrosternal position, which still has some proponants[27] but which was abandoned by us because of an unacceptably high rate of complications, in particular, anastomotic leakage and stricture formation, acid reflux, long-term recurrent respiratory infection, anaemia and diarrhoea. In addition we have observed a worse overall long-term result in terms of dysphagia.

In contrast to our experience, Lindahl *et al.*[20] showed no statistical difference in results from 34 patients with retrosternal or transthoracic interpositions. Nevertheless they observed that their single case of an anastomotic ulcer occurred in a retrosternally placed colon. In our series 35 per cent of patients with a retrosternal graft developed an anastomotic ulcer compared with none following transthoracic interposition. This difference may be explained by the increased incidence of acid reflux found after retrosternal interposition (60 per cent compared with 18 per cent after transthoracic interposition), it is perhaps not surprising as with the retrosternal approach, anastomosis is directly to the body of the stomach, whereas with the Waterston procedure it is usually to the distal oesohageal stump, thus preserving the integrity of the normal antireflux mechanisms In addition the Waterston technique has the advantage of enabling a shorter length of colon to be used to replace only that proportion of the oesohagus which is absent.

In our series and in others[12,28] there does not appear to be any advantage in staging the procedure unless the vascularity of the colon segment is in doubt[29,30]. What may be more important, however, is the timing of the procedure. It has generally been thought that the mortality rate of corrective surgery is higher in small infants with oesophageal atresia, owing to the greater potential hazard of regurgitation and aspiration. Furthermore, in the absence of a tracheo-oesophageal fistula, children with oesophageal atresia usually have a small colon and stomach with a poorly developed blood supply. For these reasons Waterson favours 6–12 months as the optimal age for replacement surgery. Nevertheless, Freeman[8] has recently proposed early interposition at 2 weeks following just an initial gastrostomy and Replogle tube drainage of the upper pouch So far this policy has had good results. If corrective surgery is delayed, however, sham feeding is certainly important to avoid feeding difficulties once gastrointestinal continuity has been restored.

What may also be important, particularly in view of the high incidence of chest infection and the fact that most early complications arise from vascular insufficiency, is elective postoperative ventilation to ensure adequate oxygenation during the most critical period[31]. Similarly, it is important to correct hypovolaemia and to maintain an adequate blood pressure particularly in the first few hours after surgery.

The topic of motility in the colonic conduit has caused considerable controversy. Early work based on fluoroscopy, cineradiography and manometry concluded that the conduit emptied by gravity alone and that there was no propulsive motor activity[30,32]. In support of this Sieber and Sieber[32] reported that no difference in function could be found between grafts placed in the isoperistaltic or the antiperistaltic positions However, recent work[33–36] suggests that there may be some degree of propulsive motor activity in isoperistaltic grafts, but more importantly there appears to be better clearance of an acid load. In addition Clark *et al.*[35] found prolonged periods of alkaline recordings during 24-h pH monitoring of the infradiaphragmatic colon and they have postulated that the bicarbonate-containing mucus secreted by the colonic mucosa may further help to protect against acid reflux. For these reasons and from our own experience we would not advocate antiperistaltic grafts.

Redundancy has frequently been reported after colon interposition[8,10] and may be a serious problem. However it is our experience that this is generally not so and usually no specific treatment is required although symptoms do not necessarily improve as the child grows because the colon also grows. What appears to be a more serious problem, and it may have been underestimated in the past, is haemorrhage. This occurred in 13 per cent (nine) of patients and led to graft failure in two cases.

Aspiration-induced respiratory infection occurring in the postoperative period has been well documented[12] However, to the best of our knowledge, there are no reports concerning the incidence of recurrent respiratory infections occurring on a long-term basis. In our experience 36 per cent of children complained of this problem several years after interposition. While many are also asthmatics, undoubtedly aspiration is frequently responsible. Perlmutter *et al.*[37] reported a single case of colobronchial fistula occurring 14 years after colonic interposition. Although extremely rare, this possibility should be considered where recurrent respiratory infection is a new feature and has not been present since operation.

In keeping with most other series[12], we did not demonstrate any 'catch-up' phase in the growth rate after colonic interposition for oesophageal atresia Interestingly German and Waterston[38] found no difference in weight gain between patients treated by primary anastomosis and those treated by colonic interposition, but they observed that those requiring interpositon had a consistently lower birthweight and they postulate that these patients represent a group of small-for-date babies. Long-term experience of this condition is that one-third remains small over a 5-year period[39].

The pattern of growth after interposition for an intractable stricture appears to be different from that observed in atresia patients[40], but the numbers involved in our series are too small to comment.

In common with Ahmed and Spitz[12] we have observed that many of the initial problems after colonic interposition (respiratory infection, dysphagia and so on) improve with time and we believe it is important to stress this to the family concerned, particularly as psychological disturbances related to the problems of adjustment are known to occur in both the child and the family

Whether the interposed segment of colon, which, when the operation is performed in infancy, is likely to remain *in situ* for 70 years or more, is more likely to develop diverticular disease or carcinoma than a normally sited segment of colon remains to be seen, but both conditions have already been recorded[25,41] although resection and reanastomosis have been possible

In summary, we believe that colonic interposition is a satisfactory method of oesophageal reconstruction in children with relatively low mortality and failure rates. By adopting a policy of transthoracic (Waterston) interposition we have significantly reduced our complication rate from earlier attempts using a retrosternal route, and we believe that many minor problems encountered in the early years after surgery disappear with time

Paper accepted 6 February 1989

UNIVERSITE DE LAUSANNE

Notre Faculté de médecine cherche un

professeur ordinaire de chirurgie

avec fonction hospitalière de médecin-chef du service unique de chirurgie. Une large expérience en chirurgie générale est requise, avec formation dans un domaine particulier où pourront être développées une activité clinique et une recherche de pointe.

La cahier des charges peut être obtenu au Décanat de la Faculté de Médecine.

Les offres de candidature, avec curriculum vitae détaillé et travaux scientifiques, sont à adresser au professeur Y. Saudan, Doyen de la Faculté de médecine, Bugnon 9, CH-1005 Lausanne, avant le 1er septembre 1989.

REPRINTS

Reprints of all articles in this journal are available in quantities of 100 or more.

Reprints are essential —

- for the company that wants to distribute impartial comment on its activities to potential customers and clients
- for the company that wants to up-date its technical staff on new techniques and new technologies

For full details of prices and availability of reprints, please write to

Announcement and Call for Papers

GULLET

An international journal of oesophageal disease

Gullet will cover all aspects of disorders of the oesophagus—their aetiology, investigation and diagnosis, and both medical and surgical treatment.

Gullet will provide a single forum for material currently published in a wide variety of books and journals and will keep research workers and clinicians up-to-date with the latest developments in their field.

The journal will include primary research papers, short reports, commissioned review articles, correspondence, book and equipment reviews, annotated abstracts and announcements of meetings.

It is a central aim of the journal to give rapid decisions on acceptance or rejection of submitted papers, and accepted papers will be published as quickly as possible.

Gullet will be of interest to general and thoracic surgeons, gastroenterologists, ENT specialists and radiologists.

Editors:

Dr John R Bennett
Consultant Gastroenterologist
Remenham House
197 Westella Road
Westella
Humberside HU10 7RP, UK

Professor Glyn G Jamieson
Department of Surgery
Royal Adelaide Hospital
North Terrace
Adelaide
South Australia 5000

Papers: Original research papers should be submitted to the nearest Editor.

Publication: The journal will be published quarterly. First issue: September 1990.

Further information: Requests for further information or subscription details should be sent to:
Sales Promotion Department, Churchill Livingstone Medical Journals, Robert Stevenson House, 1-3 Baxter's Place, Leith Walk, Edinburgh EH1 3AF, UK.

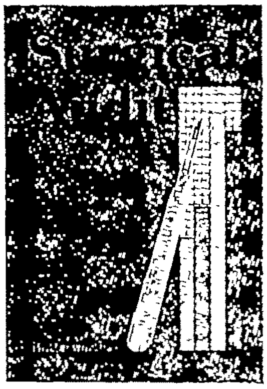
Surgical Audit

Alan Pollock BSc FRCS FRCS(Ed)
Consultant Surgeon, Department of Surgery,
Scarborough Hospital, Scarborough, UK

Mary Evans BA
Research Co-ordinator, Department of Surgery,
Scarborough Hospital, Scarborough, UK

- ★ **written by acknowledged experts in the field**
- ★ **essential reading for all surgeons with the increasing demands for quality control, patient satisfaction and cost effectiveness**
- ★ **enables surgeons to set up and evaluate their own audit systems**

This book provides practical advice on how surgeons can evaluate the various facets of surgical practice and their effective management.



Surgical Audit will be an essential book for all practising and trainee surgeons and will be welcomed by hospital administrators and all those involved in the day-to-day running of surgery departments.

Contents: The history of audit • The evolution of surgical audit • What is audit? • Economic audit introduction • Economic audit: reducing hospital stay • Diagnosis related groups and performance indicators • The containment of costs in surgery • The containment of costs of health care in the USA • Recording, retrieval and analysis of clinical data • Introduction to audit of outcome • An example from the SENIC program • Random control trials • Confidential enquiry into perioperative deaths • Quality of life after surgery • Mishap and malpractice • Measures to encourage professional competence • Introduction to audit of patient satisfaction • Waiting for hospital treatment • The sanctity of life • Clinical surgery • Human experimentation • Peer review of papers submitted to scientific journals • Audit of surgical publications • The presentation of audit of outcome • Index

Umbilical sepsis

A. S. Sroujieh and A. Dawoud

Department of Surgery, Faculty of Medicine and Jordan University Hospital, Amman, Jordan

Correspondence to:
Professor A. S. Sroujieh

Pilonidal sinus of the umbilicus is rarely reported, and there are only 17 reported cases. On reviewing the records from Jordan University Hospital, 24 patients who were treated surgically for a discharging umbilical sinus were found. Three patients had known causes for their umbilical sepsis, namely stitch sinus, urachal remnant and an umbilical polyp. Of the remaining 21 patients, seven had clinical and pathological evidence of hair in their umbilicus. Most of our patients were young men who presented with discharge, soreness or pain, swelling, and cellulitis. Treatment by umbilical excision, leaving the skin defect to heal by secondary intention, proved satisfactory. The resultant scar resembles a normal umbilicus.

Keywords: Umbilicus, sepsis, pilonidal sinus, omphaloplasty

The first description of a patient with a pilonidal sinus was by Anderson in 1847[1], and Jackson[2] described pilonidal sinus in the umbilicus in 1854. The term pilonidal sinus was first proposed by Hodges[3] in 1880. Pilonidal sinus was originally thought to be congenital in origin, but the works of Patey and Scarff[4] on interdigital pilonidal sinus in barbers, and Patey and Williams[5] on the arrangement of hair in the pilonidal sinus of the umbilicus strongly suggest that this disease is acquired[6].The case reported by Colapinto[7] proves beyond doubt that pilonidal sinus of the umbilicus is acquired as the patient was a barber and the hair found in his umbilical sinus was of different colours and therefore belonging to his customers. There are reports of 17 cases of umbilical pilonidal disease in the literature[2,5,7–20]. A further seven cases of pilonidal sinus from a total of 21 patients who presented with umbilical discharge or suppuration are presented. We propose a simple method of treatment for this disease which can be safely and effectively applied to treat the acute and chronic variety of the disease.

Patients and results

The records of 24 patients with a discharging umbilical sinus treated at Jordan University Hospital between 1979 and May 1988 were reviewed. Three patients had known underlying causes (a stitch sinus following laparoscopy, a urachal remnant, and an umbilical polyp) and were excluded from further study. The remaining 21 patients comprised 19 men and two women. Their ages ranged from 18 to 45 years with a mean age of 21 years. All patients complained of a discharging umbilicus, 13 patients had localized pain, eight had swelling with cellulitis around the umbilicus, six had pyrexia and leucocytosis, and one had enlarged axillary lymph nodes. The duration of symptoms ranged from 3 days to 4 years (mean 6 months). Seven patients (six men and one woman) had clinical evidence of hair in their umbilicus. One patient who was advised to use a dilute alcohol cleansing solution developed severe suppuration requiring emergency surgery. The degree of hirsuitism was not mentioned in the records.

Nineteen patients were treated surgically; two patients did not attend for treatment. Six patients were treated by elliptical excision of the umbilicus with primary closure. Six patients were treated by excision and primary reconstruction of the umbilicus. The remaining seven patients (treated by A.S.S.) underwent excision of the umbilicus with a surrounding disc of tissue down to the rectus sheath, a technique which we describe as omphaloplasty by secondary intention. The resulting wound was cleaned with saline daily, dressed with dry gauze, and left to heal by secondary intention. Complete healing of the wound took approximately 1 month. The resultant scar looks like a normal umbilicus, giving a very satisfactory cosmetic appearance (*Figures 1* and *2*).

The mean duration of hospital stay did not differ between patients treated by the closed method (4·2 days) and those treated by the open method (4·4 days). Two patients treated by the closed method developed wound infection requiring drainage whereas none of those treated by the open method had significant infection.

The histopathology showed evidence of acute inflammation and foreign body granuloma in all patients. In addition the presence of hair was noted in seven patients.

Discussion

Pilonidal sinus of the umbilicus is a rare disease. Only 17 cases have been reported in the literature[2,5,7–20]. Goodall[12] reported 163 cases of pilonidal disease; only one involved the umbilicus, making an incidence of 0·6 per cent. It is a disease of young hirsute adult men. The only woman to be reported had an umbilical discharge without clinical evidence of hair in the umbilicus; she did not undergo surgery and Aird[8] could not have made a definite diagnosis. The mean age of reported patients was 25 years (range 18–56 years) and did not differ significantly from that in our series. Of our total series of 21 patients, seven had clinical evidence of hair in the umbilical sinus. There were two women and one of them had hair in the depths of the umbilicus. The disease affects people with different complexions as three of the cases reported had dark skin (two Indians[5,16] and one not specified[9]), thus claims that the disease occurs mostly in young hirsute Caucasian men[19] seems unjustified.

The majority of reported cases have been symptomatic[9] and the symptoms were sometimes intermittent with an average duration of 15 months (range 0·5–72 months). All our patients had symptoms and signs which were similar to those reported with an average duration of 6 months (range from 3 days to 4 years). They included pain, soreness, swelling, cellulitis, and discharge. Six patients had pyrexia and leucocytosis. Axillary lymphadenitis was recorded in one patient with marked umbilical suppuration which followed the liberal use of a cleansing solution; she was treated by emergency omphaloplasty by secondary intention as described earlier. There are four reports of coexisting pilonidal sinus of the umbilicus and sacrococcygeal region[16–19], but none of our patients had this combination. Gupta and Gupta reported a case of umbilical pilonidal sinus with urachal adenoma[20] and one of our patients with umbilical discharge had a urachal remnant.

Various treatments for pilonidal sinus of the umbilicus have been described. Hardaway[10] and Sadeghi-Nejad and Rains[9] report treatment by simple extraction of the hairs and claim healing of the sinuses. The condition of the patient reported by Mayo *et al.*[11] became worse by the use of a cleansing solution and antibiotic ointment before undergoing surgery. This was also our experience with one patient using a dilute alcohol cleansing solution. We would therefore stress the importance of keeping the umbilicus dry in addition to removing the hairs in the conservative management of this condition.

In the 17 cases of pilonidal sinus reported in the literature, surgical treatment was most commonly employed, omphalectomy with primary suture being performed on 11 occasions. Excision and primary reconstruction of the umbilicus was performed on three occasions[7,19,20], and in one instance it was preceded by incision and drainage 6 weeks earlier for severe suppuration[7]. Nineteen of our patients were treated surgically. A simple method of treatment for this condition (omphaloplasty by secondary intention) is proposed. It is safe and can be used as a definitive treatment in all patients with different grades of infection, avoiding the need for incision and drainage as an initial step in those with suppuration, and finally on healing it creates a new cosmetically acceptable umbilicus.

Direct method of measuring venous ulcers

P. D. Coleridge Smith and J. H. Scurr

Department of Surgery, The Middlesex Hospital, London W1N 8AA, UK
Correspondence to: Mr P. D. Coleridge Smith

In venous ulcer studies the end-point is complete re-epithelialization, but it is useful to know the initial ulcer area and healing rate. Several methods have been described for measuring ulcers, the simplest involving measurement of the length of the long and short axes using a ruler[1,2] or tracing the ulcer outline on to a transparent plastic sheet. The digitizing tablets of computers and photographic techniques have been used to estimate areas and circumferences[3–7]. The complex three-dimensional technique of stereophotogrammetry has also been applied to this problem[8].

None of these techniques gives an immediate indication of ulcer size. A device that makes direct measurements, without intermediate steps, may save time and increase accuracy. We have used a sonic digitizer (GP-7 Grafbar model, Scientific Accessories Corporation, Southport, Connecticut, USA) for measuring venous ulcers and compared this with other techniques. The digitizer has a stylus with an ultrasonic pulse generator at its tip (*Figure 1*). The pulse is initiated by a hand-held microswitch and picked up by two point microphones. Internal timing circuits enable the position of the stylus to be estimated to an accuracy of 0·1 mm. The Cartesian co-ordinates of the digitized point were then sent to a BBC microcomputer (Acorn Computers Ltd., Cambridge, UK) to display the traced shape on the screen, and to calculate the area and circumference of the traced object.

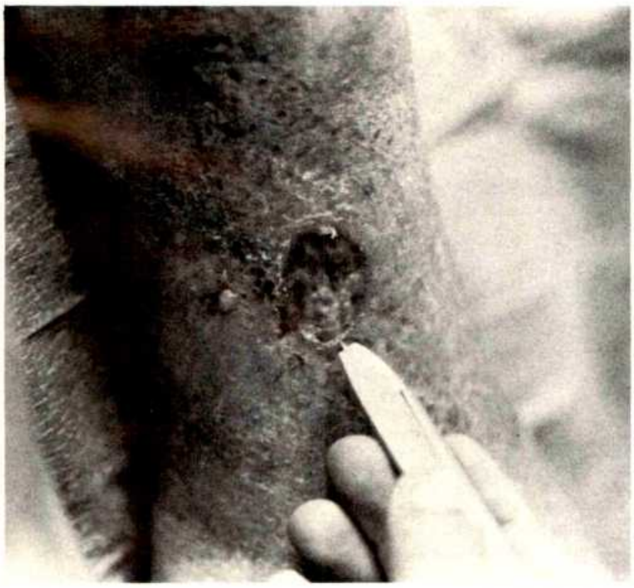

Figure 1 *The sonic digitizer used to measure an ulcer. The stylus is used to point to the edge of the ulcer, while the traced shape appears on the computer screen. The computer also calculates the area and circumference of the ulcer*

The ulcers of 32 patients attending the venous clinic at the Middlesex Hospital were measured by three techniques, each being used three times and average figures calculated for circumference and area:

1. The ulcer was traced on to a transparent plastic sheet of uniform weight. The circumference and area were measured using a digitizing tablet (MOP, Kontron, FRG)
2. The traced areas were then cut out and weighed on a laboratory balance to a resolution of 100 μg, allowing calculation of the area
3. The sonic digitizer was positioned so that the ulcer was in the active digitizing area, ensuring that sound reached the digitizer microphones by travelling over the surface of the leg, correctly indicating the dimensions of the ulcer. The digitizer stylus was used to point to the edge of the ulcer at 5-mm intervals while pressing the push-button switch to initiate ultrasonic pulses. The ulcer outline, area and circumference were displayed on the screen of the microcomputer. Large or circumferential ulcers were measured in two or more sections.

The regression line and Pearson's correlation coefficient for the sets of data were calculated using the least squares technique. The correlation coefficient between the weighing technique and the sonic digitizer was 0·98, and between the MOP area measuring device and the sonic digitizer it was 0·99. The correlation coefficient between the circumference measured indirectly by the MOP and the sonic digitizer was 0·995. In each case the slope of the regression line was very close to 1, lying in the range 0·98–1·02.

There was no difference in the time required to trace the ulcers with the sonic digitizer or using a plastic sheet, about 30–60 s being required for either technique depending on the size and shape of the ulcer. The area or circumference was immediately available from the sonic digitizer, but further time-consuming cutting or tracing was necessary to find the area by either of the other two techniques. These results confirm the accuracy of the sonic digitizer as a rapid and useful method of measuring venous ulcers.

The cost of the digitizer is £1500 sterling including software, which is also available for IBM compatible computers (PMS Instruments Ltd., Maidenhead, UK).

Intraoperative immunostaining for detection of invasive cells at the resection margin of Borrmann type 4 gastric carcinoma using monoclonal antibody S202

T. Yokota, T. Yamaguchi, K. Sawai and T. Takahashi

The First Department of Surgery, Kyoto Prefectural University of Medicine, Kamigyo-ku, Kyoto 602, Japan

Correspondence to:
Dr T. Yokota

Borrmann type 4 gastric cancer is clinically characterized by diffuse infiltration with carcinoma cells. An antiscirrhous carcinoma monoclonal antibody (MAb) S202 was used in a rapid immunostaining procedure to identify the limit of tumour invasion during surgery in samples obtained from the resection margins in 37 cases of Borrmann type 4 gastric cancer. In two instances, conventional cytological diagnosis using haematoxylin and eosin staining was negative, and in another it was inconclusive; whereas by the rapid immunostaining method single cells stained darkly, indicating malignancy. In two specimens, a positive diagnosis could be made by both methods, but immunostaining of these sections served to highlight the adenocarcinoma cells against the inflammatory background: further resection was performed. This technique enables clear recognition of the infiltrating tumour cells in the frozen sections of resected specimens. The rapid immunostaining method using MAb S202 allowed accurate and rapid determination of the limit of tumour extension at the surgical margin during surgery.

Keywords: Gastric cancer, Borrmann type 4, rapid immunostaining method, monoclonal antibody S202

Borrmann type 4 carcinoma cells extend through the gastric wall without glandular formation[1–3]. At the time of surgery, it is difficult to discriminate microscopically invasive carcinoma cells from inflammatory cells at the resected surgical margin using a frozen section technique. In addition, as the malignant cells are dispersed and resemble reactive inflammatory cells, staining with haematoxylin and eosin does not always permit identification of malignant cells by standard cytological criteria.

Our attention has been focused on the detection of antigens specific for carcinoma cells, but not inflammatory cells. Such antigens were found in the cytoplasm of gastric cancer cells (*Figure 1*). Monoclonal antibody (MAb) S202 was generated by using an intact scirrhous gastric carcinoma cell line, MK-01, for immunization[4–7]. A previous study indicated that immunoperoxidase staining can be performed within 15 min using biotin-labelled MAb S202[6]. This method has been evaluated to determine the limit of invasion of Borrmann type 4 gastric cancer at the resection margin during surgery.

Patients and methods

In 37 cases of Borrmann type 4 gastric carcinoma, specimens were obtained from the resection margin of the tumour at the time of surgery. Immediately after being cut, the frozen sections were fixed with acetone for 3 min. The staining procedure has been described previously[6]. Briefly, the sections were treated with biotin-labelled S202 (20 μg/ml) for 5 min, and avidin–biotin peroxidase complex for 3 min, with a 10-s phosphate-buffered saline wash between each step. The immunoperoxidase was made visible by incubating the sections with a solution of 0.06 per cent diaminobenzidine and 0·01 per cent H_2O_2 in Tris buffer (pH 7·4) for 3 min. The slides were finally counterstained with haematoxylin for 1 min and mounted.

The histological differentiation of the tumours was graded from the haematoxylin and eosin stained sections. The tumours were graded according to the predominant histological pattern of differentiation. The resection margin with a rim of at least 0·5 cm of normal mucosa surrounding the resected tumour and not containing tumour cells was defined as tumour-negative. When single cells stained with haematoxylin and eosin were judged to be malignant by conventional cytological criteria, the sections were defined as positive. When the diagnosis of cancer was difficult by cytological criteria, the sections were judged as suspicious. When staining with MAb S202, a clearly defined dark-brown precipitate in the cytoplasm of single cells was judged as positive. The results of haematoxylin and eosin staining and immunostaining of the frozen sections were compared later with those obtained on the permanent formalin-fixed slides.

Results

Eight of the 37 specimens had a signet-ring-cell carcinoma and the others were poorly differentiated adenocarcinoma. In two cases, conventional cytological diagnosis using haematoxylin and eosin staining was negative and in another it was suspicious, but the immunoperoxidase findings were positive (*Table 1*). The immunostained cells were clearly distinguished from the inflammatory cells (*Figure 2*). In two specimens, the diagnosis was positive with both methods.

In cases diagnosed as positive, further resection was performed. The results were confirmed later by those obtained on the formalin-fixed slides.

Discussion

At the time of surgery, it is important to detect whether the resected margin contains carcinoma cells, but it is difficult to identify scirrhous carcinoma cells of Borrmann type 4 microscopically, as disseminated tumour cells extend through the gastric wall without forming a definite malignant focus. As there is a high risk of leaving tumour cells at the resection margin, accurate detection of these cells is of therapeutic and prognostic importance.

We applied MAb S202, which strongly reacted with gastric carcinoma cells but not with inflammatory cells, to determine the limit of cancer invasion at the surgical margin of Borrmann type 4 gastric cancer during surgery. The ability to discriminate between carcinoma cells and inflammatory cells by the use of rapid immunostaining with MAb S202 was demonstrated on cryostat sections of tumour tissues. In this series, two cases were detected by the immunostaining method, while in a third case further resection was performed on the basis of positive immunostaining, in the presence of an inconclusive haematoxylin and eosin examination. Although adenocarcinoma cells were detected, and were suspected in one case, on cytological criteria, staining of these sections by the antibody resolved all suspicion.

The majority of scirrhous gastric carcinomas are formed by the infiltration of poorly differentiated adenocarcinoma cells that contain a small amount of mucin[1], whereas the percentage of mucin-containing signet-ring-cell carcinomas that invade beyond the submucosal layer is only 6 per cent of all scirrhous carcinomas[3]. Therefore, mucin-staining dyes are not useful for detecting malignant cells that invade beyond the resection margin. Because the MAb S202 reacted with nearly all adenocarcinomas[5], it appears reliable for detecting scirrhous carcinoma cells in a resected specimen.

Recently, several studies have reported the application of immunohistochemical techniques to supplement the diagnostic information obtained by conventional cytomorphology[8–20]. Previous reports[5] highlight some discrepancies in the histological findings of the immunoperoxidase and haematoxylin and eosin staining methods with respect to the depth of stomach tumour invasion. The invasive carcinoma cells could be detected more clearly by immunohistochemical staining with MAb S202 than by histological staining with haematoxylin and eosin. Thus, the reactivity of this antibody with scirrhous gastric carcinoma cells, but not with inflammatory cells, makes it a useful diagnostic tool.

Role of cholecystostomy in the management of critically ill patients suffering from acute cholecystitis

E. Winkler, O. Kaplan, M. Gutman, Y. Skornick and R. R. Rozin

Department of Surgery, Hadassah (Rokach) Hospital, Tel Aviv Medical Centre and the Sackler School of Medicine, Tel Aviv University, Israel

Correspondence to: Dr E. Winkler, Department of Surgery, Hadassah (Rokach) Hospital, 8 Balfour Street, P.O. Box 51, Tel Aviv, Israel

Between the years 1976 and 1985, 60 patients underwent cholecystostomy for acute cholecystitis in the surgical department of the Rokach hospital in Tel Aviv. The patients' average age was 73 years; 78 per cent were 70 years or older at the time of operation. The decision to perform cholecystostomy was taken before the operation which was performed as an emergency procedure for patients considered to be at high risk for cholecystectomy. Forty-six patients (77 per cent) had severe concomitant diseases, and 42 per cent of them had two or more associated diseases simultaneously. The cardiac risk index was high in most patients (90 per cent). Fifty-two patients recovered promptly after surgery. Five patients (8 per cent) developed significant postoperative complications. Three other patients (5 per cent) died of cardiovascular complications. Forty-two patients (70 per cent) underwent an elective cholecystectomy 6–8 weeks later with no further morbidity or mortality. Eleven patients who were at high risk had no further surgery. No residual stones were found in these patients and no relapse of the disease was recorded in the long term follow-up. Four patients were lost to follow-up. We conclude that cholecystostomy may still be used as an initial life saving procedure for critically ill patients with acute cholecystitis, and serves as a definitive procedure for patients considered to be at very high operative risk and who have no residual stones.

Keywords: Acute cholecystitis, cholecystostomy, surgical treatment

Acute cholecystitis among the elderly and debilitated may have a hazardous and atypical course[1,2]. Aggravation of systemic concomitant diseases may predominate in the clinical picture and the proper diagnosis is liable to be made late when the patients are already critically ill[2,3]. In order to prevent life threatening complications, prompt diagnosis and treatment are essential.

It is widely accepted that cholecystectomy is the procedure of choice for this condition[4]. The role of cholecystostomy in management is controversial. In the very ill patient with empyema of the gallbladder, severe concomitant disease or sepsis, cholecystectomy may carry a high operative risk. For these patients, a limited procedure might be warranted. Cholecystostomy is a short and simple procedure which could, therefore, be considered in such circumstances[4,5].

We report our experience with 60 patients who underwent cholecystostomy as an initial emergency procedure for acute cholecystitis.

Patients and methods

Five hundred and eight patients with acute cholecystitis were treated in the surgical department of the Rokach Hospital in Tel Aviv, during the 10-year period 1976–85. Sixty of these patients (11·8 per cent) underwent cholecystostomy as the initial treatment and their records were reviewed retrospectively.

There were 32 men and 28 women patients. The mean age was 73 years, with 78 per cent of patients being 70 years or older (*Figure 1*). The mean duration of symptoms before admission was 23 h (range from 6 h to 3 days). Patients were operated on within 5–26 h (mean 8 h) of hospitalization.

Diagnosis

Fever was the most common presenting sign (found in 66 per cent of the patients); this was followed by local tenderness and guarding (45 per cent), right upper quadrant mass (18 per cent), and jaundice (16 per cent). Right upper abdominal pain was the most prevalent symptom (60 per cent). Six patients were considered to be in septic shock on admission, as manifested by hypotension, oliguria and peripheral vasoconstriction. The white blood cell count was elevated in 57 per cent of the patients.

In 25 patients (42 per cent), cholelithiasis or past history of recurrent cholecystitis was obtained. In 27 patients (45 per cent) further investigation to confirm the diagnosis was necessary. Until 1979 intravenous cholangiography was the diagnostic procedure of choice in our hospital. It was performed in 18 patients. From 1979 ultrasonographic examination was used and was performed in nine of the patients. In eight patients, in whom the diagnosis was based on the clinical picture only, rapid deterioration mandated emergency intervention and precluded further diagnostic workup.

3	90	Ischaemic heart disease Congestive heart failure	Fever – 38·0 Right upper quadrant mass Local peritonitis	Sepsis Arrhythmia

Assessment of operative risk

Most patients (77 per cent) had suffered from severe concomitant diseases, contributing significantly to their operative risk. Ischaemic heart disease, presenting as congestive heart failure, recent myocardial infarction, or significant arrhythmia was found in 33 patients. Thirteen patients were bedridden owing to neurological disorders, such as hemiplegia or paresis. Eleven patients had chronic obstructive pulmonary disease, and nine suffered from chronic renal failure. Forty-two per cent suffered from a combination of two or more concomitant diseases.

Computation of the cardiac risk index according to Goldman *et al.*[6] showed that 54 patients (90 per cent) were in risk classes 3–4, which represents a high probability for fatal outcome or life threatening complications.

Operative treatment

The decision to perform a cholecystostomy was taken before operation and was based on the patient's clinical condition, assisted by knowledge of the estimated cardiac risk index[6].

Forty-three patients (72 per cent) were operated on under general anaesthesia, while the rest were operated on under local or regional anaesthesia. A right subcostal incision was used. An empyematous gallbladder was found in 53 patients. In the remaining seven, the gallbladder was already perforated with walling off by the greater omentum. Cholelithiasis (either single stone, multiple stones or 'sludge') was found in 57 patients. Three patients had acalculus cholecystitis.

The gallbladder was drained and the stones evacuated. A large bore rubber catheter was introduced into the gallbladder and drawn through a separate skin incision. The mean operation time was 20 min (range 15–30 min).

Results

Fifty-two patients showed rapid clinical improvement within 24 h. The presenting symptoms were alleviated and mental, cardiovascular and pulmonary function were stabilized. These patientls had an uneventful recovery with a mean hospital stay of 7·6 days.

Three patients (5 per cent) died within 30 days of operation (*Table 1*). All were older than 78 years, had significant concomitant diseases, and were admitted to the hospital in severe clinical condition. In these three patients death was attributable to cardiopulmonary complications. It is noteworthy that one patient refused surgery for 4 days, and was operated on in a state of septic shock (patient No. 3, *Table 1*).

Five other patients (8 per cent) had significant postoperative complications. Two patients who had unstable angina developed acute myocardial infarction. Acute renal failure occurred in two patients who had been in septic shock. The fifth patient developed a rectus sheath haematoma which was treated surgically. These patients recovered promptly with a mean hospital stay of 14·7 days.

Follow-up

Forty-two patients (70 per cent) underwent an elective cholecystectomy, 6–10 weeks after the first procedure. There were no deaths or major complications among these patients.

In 15 patients, cholecystectomy was not carried out. Cholangiograms performed through the draining tube revealed no residual stones in 11 patients. These were high risk patients with severe cardiovascular diseases and all were over the age of 79 years. The drains were removed and the patients were followed in our outpatient clinic for 1–6 years. During this period no recurrence of acute cholecystitis was detected. Four patients were lost to follow-up.

Discussion

It is generally accepted that medical therapy is ineffective in acute cholecystitis, and surgical intervention is advocated[7,8]. Diagnostic procedures should be undertaken while the patients are being prepared for surgery. Treatment of concomitant disease, correction of fluid and electrolyte imbalance, and antibiotics should be commenced. The appropriate surgical approach should then be decided upon. Recently, some authors have advocated the use of percutaneous cholecystostomy as an initial drainage technique[9–11]. The procedure has been performed in a limited number of patients and has not yet gained wide acceptance. Cholecystectomy is the ultimate solution for acute cholecystitis[12]. Many surgeons would perform cholecystostomy only when cholecystectomy is impossible owing to technical or other intraoperative difficulties[8,13]. The decision to terminate the operation with cholecystostomy under these circumstances is usually taken after extensive manipulations in a high risk patient. It seems, therefore, that to advocate cholecystectomy for all patients with acute cholecystitis might be too hazardous. Indeed the results of urgent cholecystectomy have not always been encouraging with mortality rates of up to 10 per cent and morbidity rates of up to 40 per cent[2,14,15] in the subgroup of patients over the age of 70 years.

In this report a different therapeutic approach was presented. Sixty (11·8 per cent) of 508 patients with acute cholecystitis were evaluated as being at high risk for cholecystectomy. In these high risk elderly patients with severe concomitant diseases, a short life saving procedure, namely cholecystostomy, was performed. The decision was taken before surgery, and thus a short general or regional anaesthesia and limited incision were planned. This approach minimized the operative trauma, spared the possibility of a long troublesome operation, and ensured adequate drainage of the inflamed gallbladder. The results were encouraging with low mortality (5 per cent) and morbidity (8 per cent) rates. Although this approach necessitates subsequent operation, cholecystectomy performed in 74 per cent of the survivors resulted in no mortality and only minor morbidity. Therefore the need for a second definitive operation should not be an argument against performing cholecystostomy as an initial procedure. Moreover, in eleven patients (19 per cent of the survivors) cholecystectomy was not performed because the cholangiogram showed no residual stones and the patients were still in a poor general condition and at too high an operative risk. We assume that emergency, or delayed elective cholecystectomy, in these 11 patients would have resulted in a higher rate of mortality. Frequent ambulatory observation revealed that none of our patients developed symptoms or signs of acute cholecystitis. These findings are in accordance with those of Ellis[4] who suggested that cholecystectomy should not be attempted in all patients.

As life expectancy is increasing and the incidence of gallstones increases with age[1,2], it is anticipated that a larger number of elderly high risk patients will suffer from acute cholecystitis[16]. Cholecystectomy in the elderly, critically ill patient, although the preferred treatment, carries a high risk of complications. Therefore, there is still a role for cholecystostomy in treating these patients.

In 20 post-mortem dissections, the subvesical bile duct of Luschka was noted in six specimens. Microscopic examination of ten other post-mortem gallbladders revealed small bile ducts on the gallbladder surface in five. Four cases of injury to the duct of Luschka during cholecystectomy are described and illustrated with cholangiographic and histological evidence. Post-cholecystectomy bile leaks from the drain tube, which closed spontaneously without sequelae, were noted in 9 per cent of 204 randomly selected cases and were regarded, at least in some, as being caused by a divided duct of Luschka. The practical significance of this duct during cholecystectomy is to keep close to the gallbladder wall during removal of the gallbladder, and to ligate a divided bile duct of Luschka if recognized at surgery.

Keywords: Cholecystectomy, bile ducts, anatomy, subvesical duct, duct of Luschka, biliary fistula

In 1863 Luschka[1] first described a slender bile duct passing from the right lobe of the liver in the gallbladder fossa and joining the right hepatic or common hepatic duct. Most workers have described this duct as a structure 1–2 mm in diameter which drains a variably sized subsegment of the posterior segment of the right liver lobe to empty into the right hepatic, common hepatic or, rarely, the cystic duct[2–8]. The reported incidence of this duct varies from 1 per cent[8,9] to 50 per cent[2,5]. The importance of the duct lies in its vulnerable position during cholecystectomy. The frequency of damage to the duct is not known and the techniques for avoiding or recognizing its injury have not been previously emphasized.

Materials and methods

The duct of Luschka and damage to it were studied by three methods: post-mortem dissections, operative cases and post-cholecystectomy bile leakage.

Post-mortem dissections

A series of 30 post-mortem dissections were performed. In 20, gross dissections were made with special attention being paid to the gallbladder bed and the cholecystohepatic triangle of Calot. In another ten post-mortems, three tissue blocks were taken from the undisturbed gallbladder bed and embedded in paraffin; 5-μm sections were cut, stained with haematoxylin and eosin, and examined microscopically by two independent observers.

Operative cases

Four cases of damage to the duct of Luschka during cholecystectomy which came under the care of the authors over a 12-month period were studied.

Post-cholecystectomy bile leakage

The case notes of 204 patients who underwent cholecystectomy at the Repatriation General Hospital, Heidelberg, from 1985 to 1987 were examined for evidence of a postoperative bile leak, its duration and the quantity of bile drained through the drain tube.

Results

Post-mortem dissections

Only cases without previous biliary disease were selected for examination. Twenty gross post-mortem dissections were performed. There were six subvesical ducts found (30 per cent). Five of these were placed fairly centrally within the gallbladder bed and one was in the lateral peritoneal reflection (*Figure 1*). Five of the ducts were traced to the right hepatic duct, while the sixth entered the common hepatic duct. None entered the cystic duct.

In none of these was the duct seen before dissection of the gallbladder from its bed. With standard surgical technique, remaining close to the gallbladder wall, there was no incidence of transection of the duct. Histological examination of one of these specimens showed that it was a meshwork of tiny ductules rather than a single duct.

A further series of ten post-mortem specimens was subjected to histological examination after sectioning the undissected gallbladder bed. In five of these cases, microscopic bile ducts were identified on the surface of the liver or in the adipose tissue of the gallbladder bed. They occurred either as single ducts or as groups of tiny ducts (*Figure 2*).

Operative cases

Case 1. A 47-year-old woman presented with a 2-day history strongly suggestive of acute cholecystitis. The liver function tests showed a mild obstructive picture. At operation, a distended, acutely inflamed gallbladder was found and decompressed. Calot's triangle was dissected and the cystic artery divided. The gallbladder was dissected from its bed close to the wall and an operative cholangiogram was performed (*Figure 3*). The gallbladder was removed, revealing a severed duct in its bed which was less than 1 mm in diameter. There was a significant leak of bile which was stopped by the application of a single metal clip. The leak of contrast medium

from this duct was apparent on the cholangiogram. Postoperatively, there were no complications and, in particular, no bile leak was evident. The drain tube was removed on the second day. The liver function tests improved immediately postoperatively. Histological examination of the gallbladder demonstrated that the small divided duct was intimately associated with the muscular wall but did not enter the lumen of the organ (*Figure 4*).

Case 2. A 59-year-old woman had an elective cholecystectomy for gallstones. At operation, a mucocele of the gallbladder was found with a stone impacted in Hartmann's pouch. A routine dissection of Calot's triangle and the gallbladder was performed during which a subvesical duct of less than 1 mm diameter was found in the interior reflections of the peritoneum. This was ligated at its proximal and distal ends. No operative cholangiogram was performed. Postoperatively there was no bile leak. The drain tube was removed on the second day and the patient made an uneventful recovery.

Case 3. A 24-year-old woman underwent elective cholecystectomy for gallstones. At operation, a short cystic duct was found which entered the right hepatic duct. An operative cholangiogram was performed, and the gallbladder was dissected from its bed. During this dissection, a fine subvesical duct was seen in the inferior peritoneal reflection and was ligated with metal clips. The duct was not visible on the cholangiogram, even in retrospect. Postoperatively, there was no bile drainage through the drain tube which was removed on the second day, and the patient made an uneventful recovery.

Case 4. A 53-year-old woman underwent elective cholecystectomy for a solitary gallstone. The gallbladder, which was somewhat embedded in the liver, was removed by sharp dissection close to the gallbladder wall. No cholangiogram was performed. On removal of the gallbladder, a tiny duct was seen in the inferior leaf of the peritoneal reflection, and it was leaking bile. This was ligated with a Dexon® (Davis and Geck, Gosport, UK) suture. Postoperatively, there was a leakage of 200 ml of bile in the first 36 h. This leakage then ceased and the tube was removed on the third day. There were no other complications and the patient was discharged on the sixth postoperative day.

Cholecystectomy series

In the 2-year period 1985–87, there were 318 cholecystectomies performed at this hospital. Of these, 204 cases were randomly selected. In these cases, cholecystectomy was performed without exploration of the common duct. There were eight cases (4 per cent) where no postoperative drains were used. A bile leak, defined as the presence of bile in the drain fluid reported in the case notes postoperatively, was seen in 19 cases (9 per cent). In these patients, the drain tube remained in place for an average of 6 days, with a range of 3–23 days. The amount of fluid drained ranged from 100 to 2000 ml with a mean of 740 ml. The amount of fluid drained per day ranged from 30 to 270 ml, with a mean of 120 ml per day. In all cases, bile leakage stopped and there were no persistent biliary fistulae. In one of these cases (0·5 per cent), a second procedure was required to drain a bile collection. At operation, the source of the leak could not be identified.

Discussion

The dissections have confirmed the occurrence of the duct of Luschka in a substantial number of cases. This is also the first report of the 'duct' occurring in the form of a meshwork or leash of tiny ductules. Also, microscopic bile ducts were found distributed within the connective tissue of the gallbladder bed, as has been described for subserosal ducts in other sites[4]. The duct was found to occur at two main sites in the gallbladder bed, most commonly in the centre of the bed but also in the lateral peritoneal reflection. In none of the post-mortem dissections was the duct visible before dissection of the gallbladder from its bed. All these features make its surgical

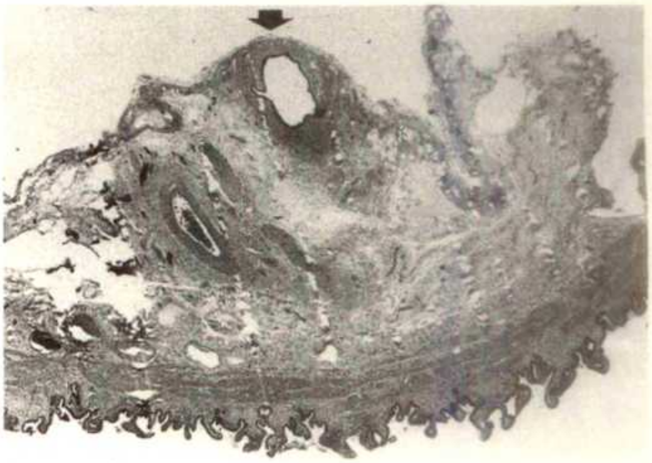

Figure 4 *Case 1. Section of the gallbladder wall and its bed with the duct of Luschka shown by an arrow. (Haematoxylin and eosin, original magnification × 10)*

identification difficult, and our clinical experience with operative cholangiography was generally not rewarding in identifying the duct.

There are differing opinions about whether the intrahepatic area drained by the duct has alternative routes of drainage or whether there are no intersubsegmental communications[4,6,8]. It is not proved, but it is the belief of the authors that intercommunications do exist, as all damaged subvesical ducts stop draining bile spontaneously without sequelae, whereas damaged major bile ducts may not[2,10].

The surgical significance of injuring the duct lies in the production of a bile leak. Several recent studies[11–13] have suggested that the incidence of fluid collections is not affected by the presence of a drain and that drain tubes promote other complications, such as pulmonary atelectasis and wound infection. However, these studies involved quite small numbers. Hoffman and Lorentzen[14] have made an extensive review of the literature and in 8423 cases found a slightly higher incidence of bile collections in the drained group (0·66 per cent) than in the non-drained group (0·27 per cent), but they were unable to exclude selection bias. They also point out that most studies report the incidence of 'fluid drainage' and the true incidence of bile in that fluid is uncertain. We have taken care in our retrospective review of operative cases to include only those cases where a definite leakage of bile has been observed by medical staff. The incidence of postoperative bile leakage in the present series was, surprisingly, not small (9 per cent). Our series cannot identify which of the leaks were due to a severed subvesical duct. However, it is the belief of Kune[2] that a sloughed or slipped ligature on the cystic duct is a rare event, so it seems reasonable to presume that at least a proportion of these leaks were due to a severed duct of Luschka.

The cases reported here also demonstrate that if the injury is recognized and dealt with at the time of operation, then the risk of bile leakage is minimal and postoperative recovery is normal. Some authors have reported repairing ducts of this size[9] in the belief that this maintains function in the drained area of liver. The authors believe this to be unnecessary and advise simple ligation. To avoid damaging the duct, it is recommended that the surgeon remain close to the gallbladder wall during its removal. However, in one of the reported cases (case 1) the duct was so intimately related to the wall that even the most meticulous technique could not have avoided its division. This strengthens the case for routine postoperative drainage after cholecystectomy.

In conclusion, the surgical significance of the duct of Luschka is firstly to recognize and prevent injury by keeping close to the gallbladder wall during cholecystectomy, and secondly to under-run or ligate the ends if an accidental division of the duct is recognized.

The role of vascularity as a prognostic factor was investigated in 35 patients undergoing arterial chemotherapy for liver tumours. Compared with parenchyma, tumour vascularity was classified as hot (18 cases), cold (12 cases), and mixed (12 cases) using ^{99m}Tc-macroaggregated albumin (MAA) hepatic arterial scans. The proportion of patients showing complete and partial responses to treatment was higher in the hot group (56 per cent) than in the combined cold and mixed group (12 per cent). In 15 cases (six hot, six cold and three mixed lesions), additional MAA scans were performed immediately after arterial embolization with degradable starch microspheres (DSMs). Either complete or partial reversal of tumour vascularity was observed after DSM-embolization in five and seven cases respectively, two and two of them respectively showing native cold lesions. As tumour vascularity appears to be a prominent prognostic factor, DSM-embolization should improve the efficacy of treatment by improving liver extraction of drugs and causing flow redistribution towards hypovascular areas.

Keywords: Liver neoplasms, drug therapy, radionuclide imaging, surgery, liver circulation, microspheres

Both animal and human studies have demonstrated that liver tumours, unlike liver parenchyma, are supplied mainly by the hepatic artery[1,2]. Thus, the arterial route is generally thought to be the most valuable single access for regional treatment of liver tumours. Higher concentrations of drugs should be achieved in the tumour than in the parenchyma and systemic toxicity should be reduced due to the first pass extraction.

A great variability of flow patterns, however, is a characteristic of tumour circulation[1,3]. Consequently, tumour masses can have either 'hypervascular' (hot) or 'hypovascular' (cold) appearances as evaluated by both standard arteriograms[4] and ^{99m}Tc-macroaggregated albumin (MAA) hepatic artery perfusion scans[5–9]. These appear to reflect the respective arterial flow and the flow-related drug distribution to the tumour and to the parenchyma. Indeed, tumour vascularity has been identified as a prominent prognostic factor in regional chemotherapy of liver tumours[4–9]. Thus manipulation of intrahepatic arterial flow should be useful in increasing the regional advantage of intra-arterial chemotherapy, particularly in cold masses. For this purpose, vasoactive drugs[10], degradable starch microspheres (DSMs)[11,12] or drug-loaded microspheres[13] can be employed.

DSMs (Pharmacia AB, Uppsala, Sweden) consist of glucose polymers cross-linked with epichlorohydrine bridges to form spheres with a mean (s.d.) diameter of 40(5) μm, being degraded by serum α-amylases with a $t_{\frac{1}{2}}$ of 15–30 min at 37°C *in vitro*. Once injected into an artery, they block flow at the arteriolar–capillary level, but this is fully reversible even after repeated administration[14]. During degradation, they maintain their size and shape until they finally collapse, allowing the blood flow to recommence[15]. DSMs have been used to slow blood flow in several organs, including small bowel, kidney, and liver[11,12]. The administration of 90×10^6 parts of DSMs into the hepatic artery proper reduces the arterial blood flow by approximately 80 per cent[16]. Consequently, the short-lasting slow-down of arterial flow following a single bolus injection of DSMs into the hepatic artery has been used to improve the extraction of a concurrently infused drug by the liver as a whole, and to reduce systemic toxicity. A reduced systemic spill-over owing to increased uptake by the liver has been demonstrated for 5-fluorouracil (5-FU)[15,17], mitomycin C[18,19], carmustine[16], and doxorubicin[20].

As DSMs have a tendency to go preferentially to high flow areas[21], the arteriolar capillary blockade should prevail in these areas, thus producing an increased arterial back pressure that would forcibly redistribute the residual arterial flow towards previously ischaemic areas. The present report assesses the possibility of modifying tumour vascularity by distal embolization of the hepatic artery with DSMs.

Patients and methods

Thirty-five patients undergoing intra-arterial chemotherapy for biopsy-proved liver tumours were investigated. The study was carried out in all cases according to the ethical standards of the Committee of Human Experimentation of our Institute. There were 22 men and 13 women, with a median age of 62 years (range 44–75 years) and median performance status of 1 (Eastern Co-operative Oncology Group: ECOG). Thirty-one patients had colorectal liver metastases and four had primary liver tumours (three hepatocarcinomas and one cholangiocarcinoma). A complete staging was carried out routinely, including: blood and urine examinations, abdominal computed tomographic (CT) scan, plain chest X-ray, superselective arteriogram, ^{99m}Tc-sulphur colloid scan, and ^{99m}Tc-macroaggregated albumin (MAA) angioscintiscan. All cases in this report had normal hepatic arterial anatomy and detectable liver tumours by MAA, sulphur colloid and CT scanning. The degree of liver replacement, as demonstrated by CT scan, was lower than 25 per cent in seven cases, between 25 and 50 per cent in 18, and higher than 50 per cent in ten. Regional access was obtained surgically with either Infusaid-400 pumps (Infusaid Incorporated, Norwood, Massachusetts, USA) or implantable ports, the catheter being inserted into the gastroduodenal artery up to its ostium[22]. The gallbladder was removed, and all vessels downstream of the catheter were interrupted.

A hepatic artery perfusion scan was performed in all cases shortly after the operation using 5 mCi MAA infused through the arterial catheter at a flow rate of 0·1 ml/s (3 ml). The catheter was then flushed at the same flow rate with 3 ml heparinized saline. Imaging was accomplished with a wide-field-of-view, single-crystal γ camera with a low energy, general purpose, parallel hole collimator. The camera was placed to include the liver and lungs excluding lung apices. After the dynamic study, the anterior, posterior, and lateral views of the abdomen and lungs were acquired with a Digital computer PDP 11/34, collecting

500000 counts on a matrix 128×128. Images were visually inspected by two experienced nuclear medicine specialists and compared with the conventional ^{99m}Tc-sulphur colloid scan. Indeed, even in comparison with computer assisted study of bidimensional regions of interest, visual inspection of the three projections appeared to give the best evaluation of vascularity in limited areas of the liver after MAA scans[7,9]. The distribution of MAA in the obvious tumour masses was classified as 'hot' (hypervascular) or 'cold' (hypovascular) when tumour uptake was compared with that of normal parenchyma. Tumours were classified as of 'mixed' type when there was gross coexistence of the two vascular patterns. Finally, images were inspected visually to identify any significant uptake in the lungs. These determinations were made without knowledge of the patient's clinical data.

Additional perfusion scans were performed in 15 patients 2–7 days after the first perfusion scan had shown hypervascular, hypovascular and mixed patterns in six, six, and three cases respectively. They were carried out with the above mentioned schedule immediately after infusing from 45×10^6 to 90×10^6 parts of DSMs through the arterial catheter. The total amount of microspheres was suspended in 50 ml of normal saline and, to avoid sedimentation, the syringe containing the mixture was shaken for 30 s before, and continuously during, the injection. Liver enzymes were monitored after DSM-administration. The differential patterns of vascularity in the obvious tumour masses were noted in each patient and the individual changes were attributed to the arterial flow redistribution caused by distal embolization with DSMs.

The cases evaluated in this report were studied during consecutive prospective phase II multicentre trials. Chemotherapy regimens were as follows: (1) continuous intra-arterial 5-fluor-2'deoxyuridine (FUdr), 0·3 mg/kg per day, from day 1 to 14 every 28 days (nine colorectal, one hepatoma); (2) bolus intra-arterial epirubicin, 30 mg, day 1 every 7 days (ten colorectal, two hepatoma, one cholangiocarcinoma); (3) bolus intra-arterial cisplatin, 40 mg/m^2 per day, from day 1 to 3 every 21 days + bolus intravenous 5-FU, 200 mg/m^2 per day, from day 1 to 5 every 21 days (seven colorectal); (4) continuous intra-arterial 5-FU, 20 mg/kg per day, from day 1 to 5 every 28 days (two colorectal); (5) continuous intra-arterial and intraportal 5-FU, 500 mg/m^2 per day, from day 1 to 5 every 28 days + bolus intra-arterial and intraportal mitomycin C, 10 mg/m^2, day 1 every 28 days (three colorectal). Due to the relative heterogeneity of clinical material, the prognostic value of MAA scanning on survival times has not been considered. However, as the proportions of both responses and vascularity patterns appeared well balanced in the different treatment groups, the relationship between vascularity and responses was analysed.

The liver responses to chemotherapy were evaluated by CT and/or echoscans every second month. The evaluation of the single lesions was made by surface area approximation, multiplying the longest diameter by the greatest longitudinal diameter. In the case of multiple lesions the products of the diameters of all lesions were summed. Complete response, partial response, minor response, stable disease, and progressive disease were designated as follows: complete response, disappearance of all known disease, as determined by two observations; partial response, a 50 per cent or greater decrease in total tumour size of the known lesions, as determined by two observations and no appearance of new lesions or progression of any lesion; minor response, 25–49 per cent reduction of tumour size without appearance of new lesions or progression of any lesion, as determined by two observations; stable disease, a less than 25 per cent decrease in total tumour size cannot be established or less than 25 per cent increase in the size of one or more measurable lesions; progressive disease, a 25 per cent or greater increase in the size of one or more measurable lesions, or the appearance of new lesions.

To determine whether the proportions of responders and non-responders among those patients with hot, cold or mixed vascular patterns were similar, patients were analysed in two-by-two tables with the two-tailed Fisher's exact probability test.

Results

Table 1 reports the number of therapeutic responses in the 35 patients matched with the degree of liver replacement and tumour vascularity, as evaluated by MAA perfusion scan. Owing to the small number of personal cases studied in each of the co-operative chemotherapy trials (the number of cases being 10, 13, 7, 2, and 3), the results of the various treatments are reported together. Indeed, the overall response rates of colorectal liver metastases in three of the above mentioned co-operative trials (National Register of Implantable Systems, unpublished data) were 38 per cent with FUdr (treatment (1), 71 cases overall), 36 per cent with epirubicin (treatment (2), 22 cases), and 47 per cent with cisplatin + 5-FU (treatment (3), 44 cases). In the different treatment groups, the proportion of pretreated cases and vascular patterns appeared well balanced, and similar response rates were shown by both colorectal metastases and primary tumours.

The simple pretreatment MAA perfusion scan showed hot, cold and mixed patterns in 18, 12 and five patients respectively. The frequency of complete + partial responses was significantly higher ($\alpha < 0{\cdot}05$) in the hypervascular than in the hypovascular group ($P = 0{\cdot}02$). Significant differences in response (complete + partial responses) were also observed when mixed cases were added to either group ($P = 0{\cdot}042$, or $P = 0{\cdot}016$ respectively). When only colorectal metastases were considered, the frequency of responses, including minor responses, was significantly higher ($P = 0{\cdot}039$) in the hypervascular + mixed group (17 and four cases respectively) than in the hypovascular group (ten cases). Furthermore, both in the entire series and in patients with colorectal cancer, the hypervascular and mixed groups showed a higher frequency of patients with a liver replacement of less than 50 per cent. The response rate was also much higher in these cases.

Five patients undergoing DSM-embolization showed from WHO grade 1 (four cases) to 2 (one case) short-lasting elevations of liver enzymes. Six patients experienced mild to moderate short-lasting pain, while severe pain and vomiting occurred in two patients. Profound changes in liver perfusion, as evaluated by MAA arterial angioscanning, were observed in most cases after DSM-embolization (*Table 2*). In four cases, very limited portions of the organ were visible, suggesting an almost complete stoppage of arterial circulation. In two of them, reflux of tracer in the stomach and duodenum was observed, while a significant but subclinical pulmonary shunt was detected in one additional patient. Regarding arterial perfusion of tumour masses, compared with liver parenchyma, DSM-embolization induced a reversal of tumour vascularity patterns in two cases with hot masses and in two cases with cold masses at the previous examination. Mixed appearances were observed after DSM-administration in two and three cases which had previously shown cold and hot patterns respectively. Two of three cases showing mixed patterns at the first examination developed hot appearances, while a complete redistribution of tumour blood flow was seen in the third patient. The behaviour of such a case is illustrated in *Figure 1*.

Discussion

The low flow MAA arterial perfusion scan appears to give a useful and reproducible estimate of the relative arterial inflow to liver tumours and parenchyma[7–9]. Indeed, despite some minor differences in examination technique, the reported frequency of pure hypervascular lesions ranges between 58 and 60 per cent, with very similar figures (59–62 per cent) when only colorectal metastases are considered. As mentioned above, the obvious value of the examination is the identification of those cases able to take maximal regional advantage from intra-arterial chemotherapy.

The results of our study are consistent with the observations that tumour vascularity is a prominent prognostic factor in regional treatment of liver tumours[7–9]. The heterogeneity of our chemotherapy schedules is not likely to affect the results substantially, as similar response rates have been observed with the different treatments, both in our co-operative trials and in the literature[23]. In the report by Daly *et al.*[9], MAA scans provided a good positive correlation between tumour perfusion and treatment responses in 47 patients with colorectal liver metastases undergoing hepatic arterial infusion of FUdr. In addition, a trend ($P = 0{\cdot}08$) toward improved survival of the 'hypervascular' group was demonstrated. This suggests that in some patients the lack of response to treatment could be related to poor perfusion of either the entire tumour or portions of it. Only low concentrations of drug are likely to reach hypovascular areas, where 'dormant' cells could be responsible for subsequent disease progression.

Several patients in our series showed pure hypovascular lesions, while hypovascular and hypervascular areas coexisted in others. This variability of arterial flow patterns appears to reflect the irregular nature of tumour angiogenesis and its relationship with the dual vascular supply of the liver. As a rule, metastatic emboli and very small tumours are mainly nourished by portal blood whereas the arterial fraction of flow becomes predominant as tumour volume increases[1–3]. This is due to arterial hypervascularization of the proliferating peripheral ring, while hypovascularization, with ischaemia and perhaps necrosis, develops in central areas. Consequently, both

DSM, degradable starch microspheres; * reflux to splanchnic organs; † complete reversal of flow patterns; ‡ heavy shunt to the lungs

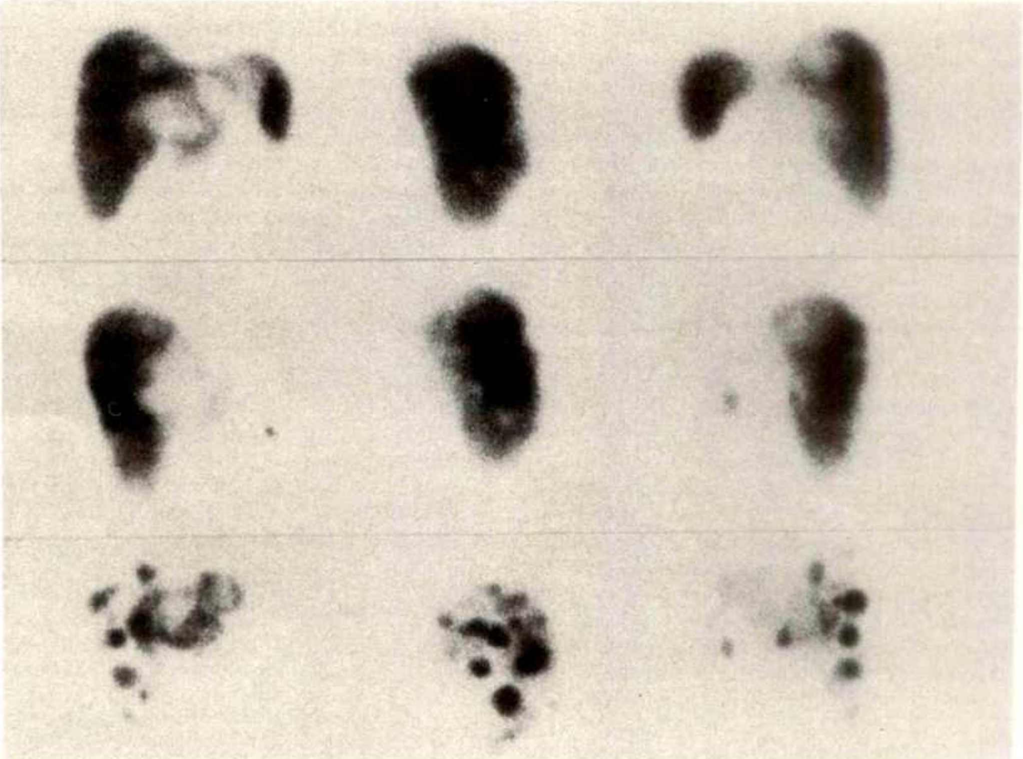

Figure 1 *A large lesion located in the left lobe and several smaller lesions located in the right lobe of the liver were identified with the sulphur colloid scan (top). They were classified as grossly hypovascular according to the first ^{99m}Tc-macroaggregated albumin (MAA) perfusion scan (middle). Compared with the parenchyma, a redistribution of flow towards all tumour areas is apparent in the second MAA scan, performed immediately after treatment with degradable starch microspheres (bottom). The relative residual hypoperfusion of the large mass, compared with the smaller ones, conforms to a substantial degree of central necrosis detected by ultrasound examination*

large and small tumours can have a very poor arterial inflow, and differential perfusion patterns can be demonstrated even in limited sections of central or peripheral areas of any kind of tumour. For this reason we established a category of 'mixed' lesions.

The lack of predictive value of the MAA perfusion test in non-responding patients with hypervascular masses may be explained, at least in part, by the relative inaccuracy of the examination. Even in the presence of hypervascular lesions, there may be hypovascular areas of the liver which cannot be shown by this kind of test. This assumption is supported by the results of CT examinations of metastasis-bearing livers using a new contrast medium (EOE-13) compared with MAA angioscan[24]. Finally, even the precise and complete definition of vascularity of the tumour cannot predict the subsequent vascularity of every single lesion; vascularity is known to undergo profound modifications with time, related to both the tumour growth and the effects of regional treatment[25].

The main purpose of our study was to investigate the possibility of manipulating intrahepatic arterial flow in man. Previous studies were performed in four patients with defective perfusion of an entire lobe of the liver after occlusion of aberrant hepatic arteries. After arterial embolization with DSMs, flow was redistributed towards the lobe supplied by the occluded artery in all cases[26]. The results of the present study, using low-flow MAA angioscanning, confirm preliminary observations with high-flow dynamic CT scanning[27]. In both cases a redistribution of flow towards hypovascular tumours can be shown after administration of DSMs in patients with normal hepatic arterial anatomy.

The induction of homogeneous perfusion of intrahepatic tumours appears to be of clinical value, as the changes induced by DSMs in tumour perfusion could increase drug uptake by the non-responsive hypovascular lesions. Although a direct correlation has been shown between tumour vascularity (MAA retention) and tumour FUdr levels during intra-arterial chemotherapy in humans[28,29], no data are yet available about the influence of DSM-embolization on changes in both perfusion and drug uptake of tumours showing different degrees of native vascularity.

The kinetics of anticancer drugs during DSM-administration have been extensively investigated in animals. Besides the increase of first pass extraction of drugs by the liver as a whole, DSM-embolization has been shown to increase not only tumour doxorubicin levels but also the tumour:parenchyma doxorubicin ratio when VX2 tumour is transplanted into rabbit hind leg[30] and liver[31]. This could be explained, at least in part, by a DSM-induced redistribution of flow to the tumour. However, as anthracyclines have a very high first pass extraction in the normal liver[32,33], the effect of DSMs could be related only to the DSM-induced slow down of arterial flow to the entire organ. Even in those cases in which DSM-embolization does not provoke changes in tumour vascularity, the first pass extraction could be increased to a greater extent in the tumour than in the parenchyma. This phenomenon could be magnified by a substantial washout of normal parenchyma owing to the portal flow. Therefore, when drugs are given mixed with DSMs in man, it seems important to correlate tumour uptake and responses not only to native vascularity but also to the changes in relative tumour perfusion induced by the microspheres themselves.

Our results indicate that distal arterial embolization with standard dosages of DSMs can be effective in redistributing arterial flow from previously 'hypervascular' towards previously 'hypovascular' areas. This phenomenon, however, has been observed only in a proportion of cases and, in some cases, only limited areas of cold lesions showed a change of vascularity after DSM-embolization. In fact, due to the excessive variability of the arterial vascularization of tumour-bearing livers, hepatic arterial embolization with standard doses of DSMs would induce highly variable effects in terms of arterial flow reduction and redistribution.

Previous studies[34] have indicated that 300–3000 mg of DSMs may have to be used to obtain complete blockage of arterial flow to the liver, as controlled by standard angiography. On the one hand, a low rate of flow reduction and redistribution may nullify the purposes of DSM-embolization, especially with regard to DSM-induced changes in perfusion and flow-related drug uptake of hypovascular masses. This can apply to those cases with hypovascular masses in which a redistribution of flow has not been shown. On the other hand, if more than the optimum amount of DSMs is given, an overflow of microspheres and drug to other organs such as the stomach and duodenum could result in severe pain and vomiting and, possibly, acute mucosal lesions. Furthermore, significant arterial–systemic shunts[35] have been described in several cases with liver tumours studied by hepatic arterial MAA perfusion scanning. After standard dosage DSM-embolization, the rise of the arterial back pressure may cause an increase of arterial pulmonary shunting which can become clinically significant even in previously non-shunting patients.

These considerations appear to be important in chemoembolization with DSMs. An ideal treatment situation is reached when the cytostatic drug is optimally retained in the whole tumour capillary bed without provoking any significant local and systemic toxicity. Consequently, there is a need to individualize DSM-dosages to obtain standard responses in terms of homogeneous distribution of flow to the tumours. For this purpose, a monitoring apparatus has been developed[34] to measure the effects of small pushes of DSMs which are injected serially into the hepatic artery until the expected effects are reached. The degree of capillary blockage is measured by the analysis of the passage through the liver of a radiolabelled low molecular weight substance devoid of hepatic metabolism (^{99m}Tc-methylene diphosphonate). It can be given arterially, mixed with DSMs and traced through the liver to the systemic circulation. The degree of arterial–systemic shunting can be monitored by measuring the systemic passage of ^{99m}Tc-macroaggregated albumin that, under normal conditions, should be almost completely stopped by the hepatic capillary bed.

Finally, the short-lasting effect of the microspheres can be fully exploited only with bolus infusions of drugs. In this setting, the drugs chosen appear to be the alkylating agents, such as mitomycin C which is known to be preferentially toxic to cells under the hypoxic conditions[36] occurring after DSM-embolization. Fluoropyrimidines, which are best given by continuous intra-arterial infusion, seem relatively unsuitable for DSM-chemoembolization. Fluoropyrimidines, however, have a definite role in regional intra-arterial treatment of colorectal liver metastases as they are the most active single agents in gastrointestinal tumours. Indeed, response rates of 55–83 per cent have been reported with combination hepatic arterial chemotherapy including mitomycin C bolus injection associated with continuous infusion of fluoropyrimidines[37,38]. On these bases, a phase I/II clinical trial has recently been activated for the regional treatment of colorectal liver metastases including regional infusion of mitomycin C + 5-FU at the dosages reported above. The total dose of intra-arterial mitomycin C is given as sequential boluses mixed with the required amounts of DSMs as defined according to the above-mentioned monitoring procedure.

Delayed recovery of hand grip strength predicts postoperative morbidity following major vascular surgery

Forearm muscle dynamometry was performed in the non-dominant arm in 61 patients undergoing major abdominal and limb vascular surgery, before operation and then 1, 3, 5, and 7 days after surgery. Six patients died in the postoperative period and seven patients developed major postoperative complications (bronchopneumonia, two; wound infection, four; myocardial infarction, one). The preoperative grip strength, measured in kilograms, of the patients who died after major vascular surgery was not significantly lower than that of patients who had an uncomplicated postoperative course. Of the 55 surviving patients, seven developed complications after surgery. These patients had significantly reduced grip strength, expressed as a percentage of the individual preoperative value (P < 0·05), from the first to the seventh postoperative day when compared with patients without complications. The delayed recovery of grip strength preceded the clinical manifestation of complications. These data suggest that delayed recovery of voluntary muscle performance may be used to detect patients developing postoperative complications and so allow their early treatment.

Keywords: Hand grip strength, postoperative complications

Major reconstructive vascular surgery carries appreciable risks of morbidity and mortality[1] owing to factors such as age of the patient and pre-existing medical problems such as myocardial ischaemia, chronic obstructive airways disease and diabetes mellitus[2]. Assessment of voluntary muscle performance by hand grip dynamometry has been used before major abdominal surgery to predict patients at risk of serious postoperative complications[3], but information about recovery of voluntary muscle performance after surgery and its relationship to postoperative complications is lacking. The aims of this study were to record hand grip strength before and after elective vascular surgery and relate this to the development of postoperative complications.

Patients and methods

Sixty-one patients (46 men and 15 women) of median age 66 years (range 41–82 years) who underwent major vascular surgical procedures were studied prospectively. The surgical procedures are shown in *Table 1* None of the patients studied suffered from active gastrointestinal or liver disease which would cause malnutrition and no patient had lost more than 10 per cent of his or her normal body weight in the 6-month period before elective vascular surgery.

Maximal voluntary hand grip strength was measured in the non-dominant arm, using a strain gauge dynamometer[4,5], in all patients before operation and again on postoperative days 1, 3, 5 and 7. Patients with diseases known to affect grip strength, such as rheumatoid arthritis and stroke, were excluded from the study. Grip strength is presented as an absolute value in kilograms for the preoperative evaluation and is matched with one of three possible outcomes, namely no complications after surgery, complications or death. Grip strength is also expressed as a percentage of the preoperative value, thus using each patient as his or her own control, for evaluation after surgery. Statistical analysis is by Student's *t* test.

Patients were reviewed daily and the definitions of postoperative complications were as follows: chest infection required a fever and chest X-ray changes; wound infection required frank discharge of pus from the wound; myocardial infarction required electrocardiographic and myocardial enzyme changes. These complications were classified as major if the patient needed to stay in hospital for more than 14 days after surgery.

Results

Six patients (four men and two women) died within 48 h of surgery, four from myocardial infarction, one from respiratory failure and one from acute renal failure. Seven patients (four men and three women) suffered major postoperative complications requiring prolonged hospitalization, comprising four wound infections, two bronchopneumonias and one myocardial infarction.

Preoperative assessment of hand grip strength, in kilograms, related to outcome is shown in *Table 2*. There was a trend towards reduced grip strength in both the men and women who died or suffered postoperative complications, when compared with patients with an uncomplicated postoperative course, but this trend was not statistically significant.

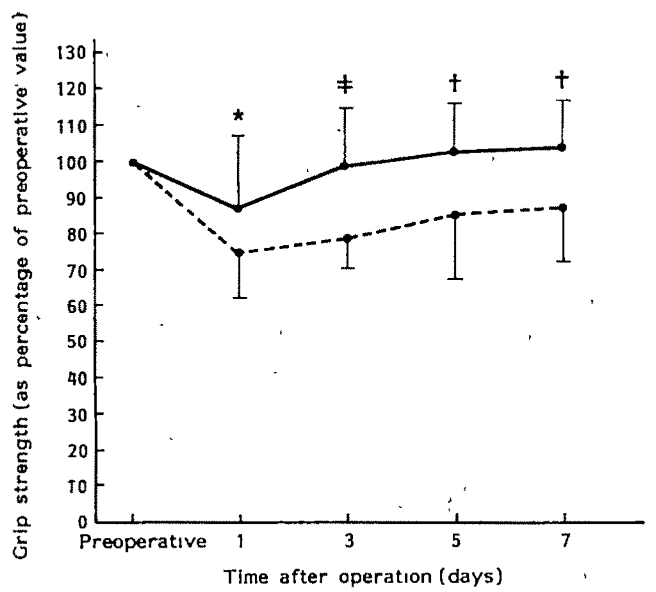

Figure 1 *Grip strength after surgery, expressed as a percentage of preoperative value, in patients with* (– – –) *postoperative complications* (n=7) *and in patients without* (——) *postoperative complications* (n=48) *the points are means with standard deviation bars.* *, $P<0\cdot05$, †, $P<0\cdot01$, ‡, $P<0\cdot0001$

All patients showed a depression of hand grip strength, expressed as a percentage of the preoperative value, after major vascular surgery. In patients who had an uncomplicated postoperative recovery, grip strength returned to preoperative levels by the third postoperative day (*Figure 1*). In the seven patients who developed major postoperative complications, grip strength was significantly lower on the first postoperative day compared with that of the patients with an uncomplicated recovery ($P<0\cdot05$) and became very significantly depressed by the third postoperative day when compared with the grip strength of the no complication group ($P<0\cdot001$). Hand grip strength remained depressed in the group with complications until the end of the study on the seventh postoperative day. The phenomenon of reduced grip strength in the patients who subsequently developed major postoperative complications was noted up to several days before the complication was clinically apparent by the previously defined criteria.

Discussion

Previous studies of voluntary muscle performance using hand grip dynamometry[3,6] have shown that reduced expected grip strength for a patient's age and sex can predict those who are at major risk of dying or developing serious postoperative complications after major abdominal surgery. Grip strength recovers rapidly after minor surgery, such as hernia repair, and operations of more stressful nature, such as cholecystectomy. This rapid recovery of hand grip strength does not correlate with the condition of postoperative fatigue which may last for months after surgery[7,8]. In our study, all patients had reduced grip strengths on the first postoperative day, but by the third day hand grip strength had returned to normal in those patients who had an uncomplicated recovery. The findings that postoperative grip strength is reduced in patients who will subsequently develop complications has not previously been reported. This phenomenon may well be of predictive value in alerting the surgeon to a patient who is at high risk of developing a major postoperative complication, enabling early appropriate treatment, for example physiotherapy and antibiotics for chest infection.

The failure of hand grip strength when taken as a single preoperative measurement effectively to predict those vascular surgical patients who subsequently die or develop postoperative complications is disappointing, as it appears to be effective in patients undergoing major abdominal surgery[3,6]. It may be that grip strength is a poor indicator of myocardial ischaemia which was the major cause of postoperative death in four out of the six patients who died in the present series. Grip strength is more effective in identifying patients at risk of septic complications[6] after surgery and is known to be reduced in patients with acute infectious diseases[9]. Why grip strength should be reduced in patients with septic complications is unknown but it may be due to impaired function of the forearm muscles responsible for grip strength. Muscle biopsies in patients with infectious diseases show reduced activity of sarcoplasmic enzymes[10,11], which may reduce the availability of energy-rich phosphates causing muscle weakness. Alternatively, apparent muscle weakness may be due to a central effect[11] as a result of disturbance of the pathway from the cerebral motor cortex to the forearm muscles.

Further research in this area should identify the level of impairment of voluntary muscle performance in patients with septic complications. For the present, the observation that the delay in return of hand grip strength to preoperative values occurs up to 48 h in advance of the developing complication is of interest, as it may allow early treatment for expected postoperative complications.

Ultrasound guided percutaneous pancreatic biopsy

C. J. Mitchell, D. Wai, A. M. Jackson and J. MacFie

Scarborough Hospital, Scarborough, North Yorkshire YO12 6QL, UK
Correspondence to: Dr C. J. Mitchell

A major obstacle to the diagnosis and understanding of pancreatic exocrine disease has been the inability to obtain histological samples safely without resort to laparotomy. Surgeons are reluctant to biopsy the pancreas in view of the recognized frequency of complications, especially using large calibre needles[1–3]. The disadvantage of fine needle aspiration biopsy for pancreatic diagnosis is that only a cytological sample is obtained.

We report our initial experience with a recently developed system of percutaneous, targeted organ biopsy under ultrasound guidance that provides a histological sample[4] which we have applied to pancreatic biopsy.

Patients and methods

Biopsies were performed on fasting, consenting patients with a normal coagulation screen. An 18 gauge Tru-cut® (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) biopsy needle was mounted in an automatic firing device employing a spring-loaded mechanism[4] (Biopty®, Radiplast AB, Uppsala, Sweden) that is operated with one hand, enabling simultaneous ultrasound scanning. The needle tip and biopsy track can be seen ultrasonically to confirm precise targeting. An initial scan is performed to plan the biopsy route avoiding the liver and major vessels as well as, if possible, the colon, although most biopsies were performed transgastrically Using an aseptic technique and local anaesthesia the needle was advanced under ultrasound guidance to the edge of the pancreas or mass lesion

Thirty-eight patients were prepared for biopsy, which was not attempted in five patients because hepatomegaly obscured the pancreas. Pancreatic biopsy was attempted in 33 patients (19 men and 14 women) aged 36–74 years (*Table 1*). The most common indication was a pancreatic mass lesion found at ultrasound in 23 patients, of whom 11 were jaundiced; 17 were considered clinically to have pancreatic carcinoma and the other six to have chronic pancreatitis. Three patients with pancreatitis had a biopsy because an unusual cystic lesion was detected. Seven patients with recurrent abdominal pain and equivocal investigations were suspected of having chronic pancreatitis.

Results

The only complication was severe abdominal pain in two patients which resolved spontaneously. Biopsy failed in two patients. Sample size varied from 13 × 2 mm to 4 × 3 mm.

The results are shown in *Table 1*. Pancreatic biopsy provided the correct diagnosis in all cases. Neoplasms were confirmed at laparotomy or autopsy. Chronic pancreatitis was diagnosed on the basis of calcification (three), abnormal pancreatograms (nine), exocrine dysfunction (five) or laparotomy (two) and all have been followed clinically for over 1 year. Whilst biopsy merely confirmed the clinical and ultrasound diagnosis in 21 of 33 patients it excluded neoplasia in four of six patients with chronic pancreatitis and an ultrasound mass. It diagnosed the non-pancreatic origin of three tumours and one unsuspected islet cell tumour and provided a diagnosis in six of seven patients with equivocal investigations. It should be noted that in four of 12 non-jaundiced patients (33 per cent) with a pancreatic mass at ultrasound, the clinical diagnosis was erroneous.

Discussion

In 1982, Lindgren[4] described a percutaneous needle biopsy technique for kidney and liver with several practical advantages. Simultaneous ultrasound scanning confirms correct biopsy targeting and a histological sample is provided. Satisfactory specimens were obtained in all cases, with one minor bleeding episode[4]. There are no published results of this technique for pancreatic biopsy, although it is mentioned in a recent review[5] that the authors' experience with 40 patients indicated a higher accuracy than with fine needle aspiration biopsy.

The results of this study suggest that it is a reliable technique. All tumours have been confirmed subsequently and patients with pancreatitis show no evidence of neoplasia on follow-up. Estimates of sensitivity and specificity are inappropriate. We have infrequently encountered the well recognized difficulty in histological distinction between carcinoma and chronic pancreatitis, perhaps because of the biopsy size. The availability of a histological diagnosis had a major impact on clinical management.

Table 1 *Indications for biopsy and results*

Indication for biopsy (number)	Initial clinical diagnosis	Number of patients	Final histological diagnosis	Number of patients
Ultrasound, mass + jaundice (11)	Pancreatic carcinoma	10	Pancreatic carcinoma	10
	Chronic pancreatitis	1	Chronic pancreatitis	1
Ultrasound, mass alone (12)	Pancreatic carcinoma	7	Pancreatic carcinoma	4
			Ampulla carcinoma	1
			Gastric carcinoma	1
			Lymphoma	1
	Chronic pancreatitis	5*	Chronic pancreatitis	3
			Insulinoma	1
Equivocal investigations (7)	Pancreas divisum	3*	Chronic pancreatitis	1
			Normal	1
	Uncertain	4	Chronic pancreatitis	3
			Normal	1
Ultrasound, cyst (3)	Chronic pancreatitis	1	Chronic pancreatitis	1
	Acute pancreatitis	2	Acute pancreatitis	2

* Biopsy failed in one patient of each group

The crucial question, however, is whether this procedure is safe. The risk of biopsy increases with the needle size employed; thus, biopsy with a 22 gauge needle carries a mortality rate of 1:20 000 and a complication rate of under 1 per cent[5,6] and, conversely, biopsy with 14 gauge needles has a mortality rate of up to 9 per cent and a complication rate of 7·5–14 per cent[1-3]. One would predict an intermediate complication rate for this technique, which should not be undertaken without a good clinical indication until its safety is established. There are few disadvantages to this biopsy technique; the equipment is inexpensive and most hospitals possess real-time ultrasound equipment and facilities for histological assessment. The main problem has been the presence of hepatomegaly obscuring the pancreas, but transgastric (usually) and transcolonic (occasionally) biopsies have not caused problems.

Relationship between bile acid malabsorption using the ^{75}Se homocholic acid taurine scanning method and diarrhoea following right hemicolectomy

A. J. Jewkes, C. W. O. Windsor, R. S. Ward* and A. E. Timmins*

*Departments of Surgery and *Nuclear Medicine, Royal Infirmary, Worcester, UK*

Diarrhoea following right hemicolectomy occurs in up to 50 per cent of patients[1]. Malabsorption of bile acids due to resection of the terminal ileum is thought to be important in the pathogenesis of these postoperative symptoms[2], hence changes in the bile acid pool have been investigated following right hemicolectomy using selenium-75 homocholic acid taurine (^{75}SeHCAT, Amersham International plc, Amersham, UK) scanning in order to define the relationship between bile acid malabsorption and symptomatic diarrhoea.

Patients and methods

To evaluate the temporal relationship between bile acid malabsorption and diarrhoea the bile acid pool was examined in 21 patients undergoing right hemicolectomy, using 7-day ^{75}SeHCAT scanning (*Table 1*) Seven patients had Crohn's disease of the terminal ileum and 14 had carcinoma of the caecum The length of unstretched small bowel resected was recorded before fixation.

A previously described method of ^{75}SeHCAT scanning was used with minor modifications[3] ^{75}SeHCAT 37×10^4 Bq was administered orally after an overnight fast. ^{75}Se activity was measured using a large field γ camera (Elscint Dymax LF, Israel) interfaced with an Elscint Dycom 80 computer. After an equilibration period of 4 h, the gallbladder area was counted with the patient supine and prone for 5 min each The procedure was repeated after 7 days and retention was expressed as a percentage ratio of the counts on day 7 to the counts on day 0

^{75}SeHCAT scanning was not possible in all cases because of partial or complete intestinal obstruction. Eleven patients were studied preoperatively, 21 patients at between 2 and 11 weeks after surgery and 18 patients at 44–80 weeks. In patients with Crohn's disease there was no clinical evidence of active disease during the study period Ten patients were treated postoperatively with antidiarrhoeal agents (*Table 1*)

Table 1 *Details of all patients included in the ^{75}SeHCAT study*

No.	Sex	Age (years)	Diagnosis	Length of ileum resected (cm)	*Diarrhoea Early	*Diarrhoea Late	Treatment

*Symptoms reported while off any antidiarrhoeal therapy; † patient died before final study. ^{75}SeHCAT, selenium-75 homocholic acid taurine

0007-1323/89/070707-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

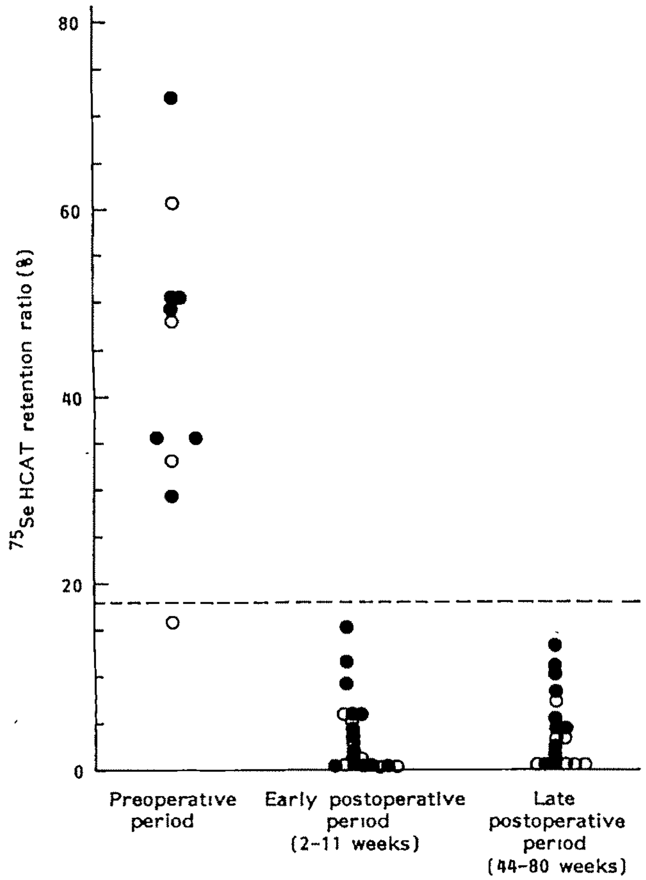

Figure 1 *Seven-day selenium-75 homocholic acid taurine (^{75}SeHCAT) retention ratios in the preoperative and postoperative periods (values <19 per cent indicate bile acid malabsorption, Reference 4).* ○, *Crohn's disease;* ●, *caecal cancer*

Medication was discontinued at least 1 week before scanning. Daily records of stool frequency and consistency were kept by each subject, while not taking medication, in the early and late postoperative periods. Diarrhoea was defined as three or more loose or poorly formed motions per day, while off treatment

Statistical analyses were performed using the Mann–Whitney *U* test and the Spearman rank correlation. Significance was defined as $P < 0.05$. The study was approved by the District Ethical Committee.

Results

The median preoperative ^{75}SeHCAT retention ratio was 44·3 per cent (range 17–73 per cent; normal value >19 per cent) compared with the significantly lower early postoperative value of 3·5 per cent (range 0–15 per cent, $P < 0.001$) and the late postoperative value of 3·0 per cent (range 0–14·5 per cent, $P < 0.001$; *Figure 1*).

The median length of small bowel resected was 27 cm (range 4–81 cm; *Table 1*). There was no significant correlation between the length of small bowel resected and the ^{75}SeHCAT retention (early postoperative period $r = 0.13$, $P = 0.59$; late postoperative period $r = 0.05$, $P = 0.84$).

In the early postoperative period ten of the 21 subjects (48 per cent) had diarrhoea (median stool frequency 4 per day, range 0·5–10 per day) compared with only three of 18 (17 per cent) in the late postoperative period (2 per day, range 0·33–6 per day, $P = 0.013$). Adequate control of symptoms was achieved using standard medication in seven of the ten patients in the early postoperative phase and in two of the three patients in the late postoperative period.

There was no significant correlation between the length of ileum resected and postoperative stool frequency, in either the early ($r = 0.17$, $P = 0.46$) or late postoperative periods ($r = -0.21$, $P = 0.41$). There was also no correlation between the degree of postoperative diarrhoea and ^{75}SeHCAT values (early $r = 0.13$, late $r = 0.05$).

Discussion

Results of ^{75}SeHCAT studies are comparable to faecal [^{14}C]taurocholate determination, but without the disadvantages of the latter technique[4] In our study, malabsorption of bile acids following right hemicolectomy was universal and supports earlier published data from a study of bile acid malabsorption following ileal resection[5]. In contradiction to earlier studies no correlation was found between the length of ileum resected and the degree of bile acid malabsorption[6]. Patients with ileal resections and intact ileocaecal valves have previously been noted to absorb bile acids better and have less diarrhoea than those in whom the valve had been removed[1]. This suggests that bile malabsorption could be exacerbated by rapid intestinal transit.

Although there was no improvement in bile acid reabsorption during follow-up, significant reduction in stool frequency occurred in seven of ten patients. Both small and large bowel adaptation may be responsible for this effect. The symptomatic improvement seen in the late postoperative period may also be the result of the return of normal intestinal flora in the colon. Anaerobic bacteria are important in generating short-chain fatty acids from dietary fibre and these can counteract the inhibitory effects of bile acids on colonic sodium and water reabsorption[7,8].

In benign disease preservation of the ileocaecal valve and the right colon seems desirable. Further studies are required to clarify the adaptive processes which appear to occur following right hemicolectomy.

Acknowledgements

The authors wish to thank Mr J. Black for permission to study his patients Special thanks to the staff of the Nuclear Medicine Department, Worcester Royal Infirmary, for their help and co-operation with this study.

Human fasting and postprandial sphincter of Oddi motility

C. S. Worthley, R. A. Baker, J. Iannos, G. T. P. Saccone and J. Toouli

Gastrointestinal Surgical Unit, Flinders Medical Centre, Bedford Park 5042, South Australia

Correspondence to:
Dr J. Toouli

Sphincter of Oddi motility was evaluated in post-cholecystectomy patients with indwelling T tubes during fasting and after feeding. A triple-lumen catheter was positioned to record from the sphincter of Oddi and duodenum. The sphincter of Oddi was characterized by phasic contractions independent of duodenal contractions. During fasting duodenal wave frequency exhibited four phases, whereas only two phases could be identified from the sphincter of Oddi. A prolonged phase A in the sphincter of Oddi corresponded to duodenal phases I, II and IV. A short phase B in the sphincter of Oddi just preceded the onset of duodenal phase III and was temporally related to it. Sphincter of Oddi basal pressure increased during duodenal phases III and IV. After ingestion of food, sphincter of Oddi basal pressure, wave amplitude and duration decreased, but the frequency remained unchanged. Conversely, duodenal frequency increased but there was no change in amplitude. Thus, the human sphincter of Oddi and duodenum exhibited independent motility demonstrating distinct phases during the interdigestive period. After food, sphincter of Oddi motility altered in a manner which would facilitate the passive flow of fluid into the duodenum.

Keywords: Manometry, biliary tract, duodenum, sphincter of Oddi

The sphincter of Oddi has a major role in the control of bile flow and flow of pancreatic juice. Studies in man and animals have shown that the sphincter of Oddi is characterized by phasic contractions which are superimposed on a modest tone[1,2]. In animals, the phasic contractions have been shown to obstruct flow transiently[3], but their main effect is to propel small volumes of fluid from the bile duct into the duodenum[4–6]. In addition, cineradiography has demonstrated some passive flow of fluid occurring between the phasic contractions[6]. Studies in man suggest a similar mechanism to that described in animals; however, the balance between active propulsion across the sphincter of Oddi *versus* passive flow remains uncertain[7–9].

In this study we have examined the motility of the sphincter of Oddi in patients who have recovered from bile duct exploration for stones and who have a T tube in the bile duct. The presence of a T tube in the bile duct permitted prolonged manometric studies to assess the interdigestive pattern of the human sphincter of Oddi and its response to the ingestion of a meal.

Patients and methods

Thirteen patients undergoing cholecystectomy and common duct exploration for stones were studied. All patients had both gallbladder and common bile duct stones and none had experienced pancreatitis in the past. There were seven men and six women with a median age of 60 years (range 40–80 years). Studies were attempted in a further six patients but failed for technical reasons. One patient experienced pain when the tip of the catheter entered the sphincteric region and in the other five the sphincter of Oddi could not be cannulated. The study was approved by the Clinical Investigations Committee of Flinders Medical Centre in May 1985, with informed written consent for inclusion in the study being obtained from all patients.

Operative procedure

Cholecystectomy was performed and bile duct exploration carried out via a longitudinal supraduodenal choledochotomy. The sphincter of Oddi was not manipulated by rigid instruments and all stones were removed. A modified latex rubber T tube was positioned in the bile duct and the duct was closed with a fine absorbable suture. The T tube was modified (*Figure 1*) by passing a 25-cm long 8 or 10 Fr soft polyvinyl chloride catheter (Nelaton®, Australian Hospital Supplies, Sydney, Australia) through the long arm and positioning its tip such that it would direct the manometry catheter towards the sphincter of Oddi. The polyvinyl chloride catheter was secured within the long external arm of the latex rubber tube with two circumferential silk sutures.

A tube choledochogram was obtained 1 week postoperatively and, if no abnormality was detected, the external limb of the T tube was occluded. The patient was discharged from hospital with the T tube *in situ*, as has been our custom, and allowed to return to a normal diet. Sphincter of Oddi manometric studies were done 1–2 weeks after closure of the T tube, thus allowing for the re-establishment of normal enterohepatic circulation of bile salts[10] and for a firm tract to form around the tube, reducing the chance of bile fistula on removal.

Sphincter of Oddi manometry was performed after a 12-h overnight fast. Medications likely to affect gastrointestinal motility were stopped on the day before study and all extraneous gustatory stimuli were eliminated.

T tube manometry

Pressure recordings from the bile duct, sphincter of Oddi and the duodenum were accomplished using a polyethylene triple lumen side

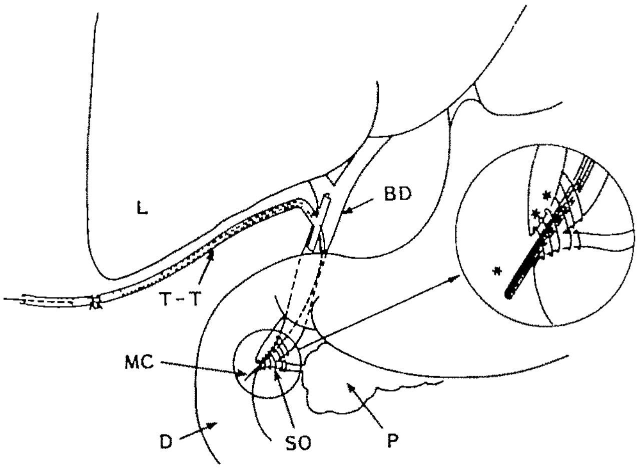

Figure 1 *Schematic representation of the sphincter of Oddi (SO), duodenum (D), bile duct (BD), liver (L) and pancreas (P) with the modified T tube (T-T) and triple lumen manometry catheter (MC) in situ. Figure 2 *Manometric recordings from the proximal (SO1) and distal (SO2) sphincter of Oddi and duodenum (DUO).* **a** *Demonstration of an activity front: its onset in the sphincter of Oddi precedes its duodenal onset.* **b** *End of activity front. the sphincter of Oddi contracts during duodenal phase I.* **c** *Duodenal phase II the sphincter of Oddi and duodenum contract independently*

hole manometric catheter, having an outer diameter of 1·0 mm, luminal diameters of 0·35 mm and a length of 1·0 m (Dural Plastics and Engineering, Auburn, Australia). The three side holes were respectively 5, 20 and 22 mm from the end of the catheter. The catheter was marked every 1 cm from the proximal side hole.

During pressure recording, each catheter lumen was infused with sterile, bubble-free water at a rate of 0·25 ml/min by a minimally compliant hydraulic capillary infusion system[11], using a reservoir pressure of 400 mmHg. Abrupt obstruction of the recording orifice of each recording lumen generated a pressure rise rate in excess of 350 mmHg/s. Each recording channel was connected via a pressure transducer to a polygraph run at a chart speed of 10 cm/min.

Recording was performed with the patient supine in bed. The external limb of the T tube was opened and the T tube and surrounding skin were disinfected with antiseptic solution. The sterilized triple lumen catheter was passed through the modified T tube into the bile duct and advanced through the sphincter of Oddi so that all three recording lumens were positioned in the duodenum. The recorded pressures were then adjusted so that duodenal basal pressure acted as the zero reference.

The manometry catheter was then withdrawn in a stepwise fashion so that the two proximal side holes were positioned within the sphincter of Oddi and the distal side hole remained in the duodenum The correct position of the recording catheter in the sphincter of Oddi was determined by the demonstration of a high pressure zone on the withdrawal of the manometry catheter from the duodenum into the sphincter of Oddi The correct catheter position was then confirmed by relating the distance the catheter was passed to the length of the T tube and the distance from the T tube to the sphincter of Oddi, as calculated from the choledochogram.

During the recording session the external arm of the T tube was left open, avoiding any increase in bile duct pressure which may have been produced by perfusion into the biliary system A small volume of bile leaked out of the open arm of the T tube and around the manometry catheter.

Preliminary recordings progressed until the first duodenal activity front was observed. This was characterized by an increase in the frequency and amplitude of duodenal contractions, followed by a period of quiescence (*Figure 2a* and *b*)[12]. If the first activity front occurred within 2 h of the start of recording and the patient was tolerating the procedure, recording continued until a second activity front was observed, thus recording a complete interdigestive cycle.

Thirty minutes after an activity front a cephalic gustatory stimulus was given: this consisted of the sight and smell of a hot aromatic meal of meat and vegetables for 1 min, followed by talk of food for a further 9 min A composite liquid test meal, consisting of 375 ml of Sustain® (Mead Johnson, Crows Nest, Australia; 13·5 g fat, 24·3 g protein, 52·5 g carbohydrate: 1750 kJ), was then ingested over 5 min Recording continued for a further 35 min or as tolerated. The total recording session lasted up to 5 h

Scoring of the manometric tracings were carried out manually and independently by two observers. Sphincter of Oddi basal pressure was referenced to duodenal pressure taken as zero and the lowest sustained sphincter of Oddi pressure for each interval was used. The amplitude of the sphincter of Oddi phasic contractions was calculated by subtracting the basal sphincter of Oddi pressure from the peak pressure. Pressure changes of less than 10 mmHg and waves characterized by an acute pressure rise rate of more than 300 mmHg/s were excluded from analysis as they represented artefacts[13]. Less than 5 per cent of total waves were excluded using these criteria. The sphincter of Oddi wave frequency was expressed as contractions per minute. Wave duration was calculated by measuring the time in seconds between the upstroke and downstroke of each contraction. Sequencing of sphincter of Oddi contractions was not determined for this study as the distance between the two lumens positioned in the sphincter would not allow accurate assessment. For analysis of the interdigestive cycle, the period between two activity fronts was normalized by division into 2 per cent intervals. The mean of the sphincter of Oddi basal pressure, wave amplitude, frequency and wave duration, were calculated for each 2 per cent interval as well as the duodenal wave amplitude and frequency. Duodenal phasic activity was analysed by adaptation of the criteria of Code and Marlett[14]. Phase I was characterized by a relative absence of phasic contractions compared with other phases. The onset of phase II occurred when the frequency of contraction was constantly greater than 1/min. Phase III started when the duodenum was contracting at the maximal observed rate Phase IV was the transitional period between phase III and the subsequent phase I.

The response to food was analysed by taking a control period of 10 min before food presentation and comparing it with the 10 min of cephalic gustatory stimuli, the 5-min ingestion period and the subsequent six consecutive 5-min intervals after ingestion For each period the mean sphincter of Oddi basal pressure, wave amplitude, duration and frequency were determined. In addition, a separate comparison was made between the mean of a 10-min preingestion period and the mean of the 20-min period immediately after ingestion.

Statistical analysis

Statistical analysis was performed using Minitab® (Minitab Data Analysis Software, University Park, Pennsylvania, USA) interfaced to a Prime mainframe computer (Prime Computer Corporation, Natick, Massachusetts, USA). Normality of distribution of the data was assessed using the Shapiro–Wilk test[15]. For normally distributed data, a paired *t* test was used and non-parametric analyses were performed using the Sign test (significance, $P < 0·05$). Data are presented in the text as mean (s.d.) unless otherwise stated

Results

In the 13 patients, a total of 19 activity fronts (*Figure 2a*) were recorded, two consecutive fronts being recorded in six patients, thus allowing normalization of six complete interdigestive cycles. Because of catheter displacement during the activity front, complete recording from the duodenum and sphincter of Oddi was not possible in three of 19 and one of 19 patients respectively, resulting in 16 duodenal and 18 sphincter of Oddi activity fronts for analysis.

Interdigestive activity of the duodenum (Figure 3)

The duodenal interdigestive cycle could be divided into four phases. Phase I consisted of a relatively quiescent period. Phase II consisted of an irregular contraction period which culminated in phase III (comprising the activity front). Phase III was characterized by a rapid contraction frequency of 11·9 (1·8) contractions/min, a wave duration of 3·9 (2·2) s and wave amplitude of 30 (7) mmHg. Phase IV then followed, during which the frequency of contraction differed significantly from phase I and phase III. The length of the duodenal interdigestive cycle was 100 (33) min.

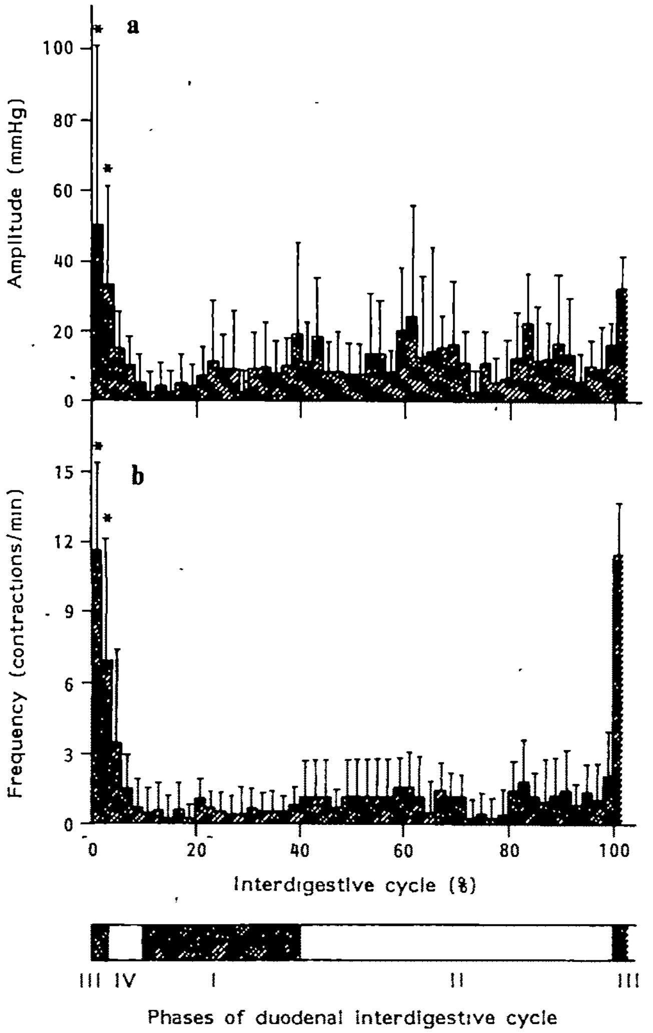

Figure 3 *Histograms of duodenal wave* **a** *amplitude and* **b** *frequency over 100 per cent of the interdigestive cycle. The interdigestive cycle is divided into 2 per cent intervals and values are expressed as the mean (s.d.) for six patients. Duodenal activity is separated into four phases and is recorded at the bottom of the figure, *denotes a significant difference compared with phases I and II*

Interdigestive activity of the sphincter of Oddi (Figure 4)

Throughout the interdigestive cycle the sphincter of Oddi demonstrated contractile activity which was visually divided into two phases (A and B).

During phase A, the sphincter of Oddi contracted at a frequency of 3·0 (1·3) min, the wave amplitude was 79 (35) mmHg and the wave duration was 5·0 (1·6) s. The basal pressure was 8 (6) mmHg and the duration of phase A was 96 (32) min.

Phase B (the activity front) consisted of a period of rapid contraction, at a frequency of 10·4 (1·4) min, lasting 4·5 (2·4) min. The wave amplitude was significantly greater during phase B compared with phase A (101 (35) *versus* 79 (35) mmHg). There was a significant increase in basal pressure during phase B (13 (6) *versus* 8 (6) mmHg), which persisted into early phase A. The wave duration did not vary significantly between phases A and B (5·0 (1·6) *versus* 5·5 (1·8) s). The length of the sphincter of Oddi interdigestive cycle was 100 (33) min.

Relationship of sphincter of Oddi to duodenal interdigestive cycle activity

A close relationship existed between the phasic contraction patterns of the sphincter of Oddi and duodenum during the interdigestive cycle (*Figure 2*).

The phasic contractions recorded from the sphincter of Oddi and duodenum were independent of each other. The sphincter of Oddi and duodenal interdigestive cycle lengths were virtually identical; however, the onset of the sphincter of Oddi activity front preceded the duodenal activity front by a median of 6 s (range 2–62 s) on all but three of the 16 occasions when complete sphincter of Oddi and duodenal activity fronts were recorded. In those three, the onsets coincided. The contraction frequency during the sphincter of Oddi activity front was significantly less than that of the duodenal front (10·4 (1·4) *versus* 11·9 (1·9) min), and the wave amplitude was significantly greater (101 (35) *versus* 30 (7) mmHg). The duration of the sphincter of Oddi activity front was significantly greater than the duodenal front (4·5 (2·4) *versus* 3·9 (2·2) min)

Although four phases were identified in the duodenal interdigestive cycle, the sphincter of Oddi only demonstrated two phases. Duodenal phases I and II coincided with sphincter of Oddi phase A, whilst duodenal phase III coincided with

The duodenal wave frequency increased but there was no change in duodenal wave amplitude*

sphincter of Oddi phase B. Duodenal phase IV overlapped the junction of sphincter of Oddi phases A and B. The sphincter of Oddi basal pressure demonstrated a significant rise during duodenal phases III and IV.

Effect of feeding on sphincter of Oddi and duodenal activity (Figures 5 *and* 6)

The sight and smell of food did not significantly alter the contractile pattern of the sphincter of Oddi or duodenum, although a trend towards a decrease in sphincter of Oddi wave amplitude was observed.

Feeding produced a significant reduction in the sphincter of Oddi wave amplitude duration and basal pressure. There was no significant effect on sphincter of Oddi wave frequency and specifically the sphincter of Oddi contractions persisted in five of the eight patients. Contractions were abolished for periods of 9, 15 and 18 min respectively in the other three patients. Duodenal wave amplitude did not alter significantly after food but there was a significant increase in frequency.

Effect of modified T tube and manometry on the patients' clinical progress

The modification of the T tube did not alter the management of the patients included in the study. Length of hospital stay was no different to that of patients who were not studied and there were no complications that could be attributed to the modified T tube. The patients tolerated the manometric studies without complication and on completion of the study the T tube was removed. Follow-up of these patients 1 month after the studies revealed no abnormalities that could be attributed to either the modified T tube or the manometric study.

Discussion

In this study we evaluated the motility of the human sphincter of Oddi during the interdigestive period and after a meal. We related the activity of the sphincter of Oddi to that of the duodenum during both the fasting and postprandial periods. The major findings from this study were:

1. The sphincter of Oddi demonstrated phasic contractions which were independent of duodenal contractions
2. In the interdigestive period the sphincter of Oddi contractions showed two distinct phases: a prolonged phase of continuous contractions which corresponded to duodenal phases I, II and IV contractions, and a short phase of rapid

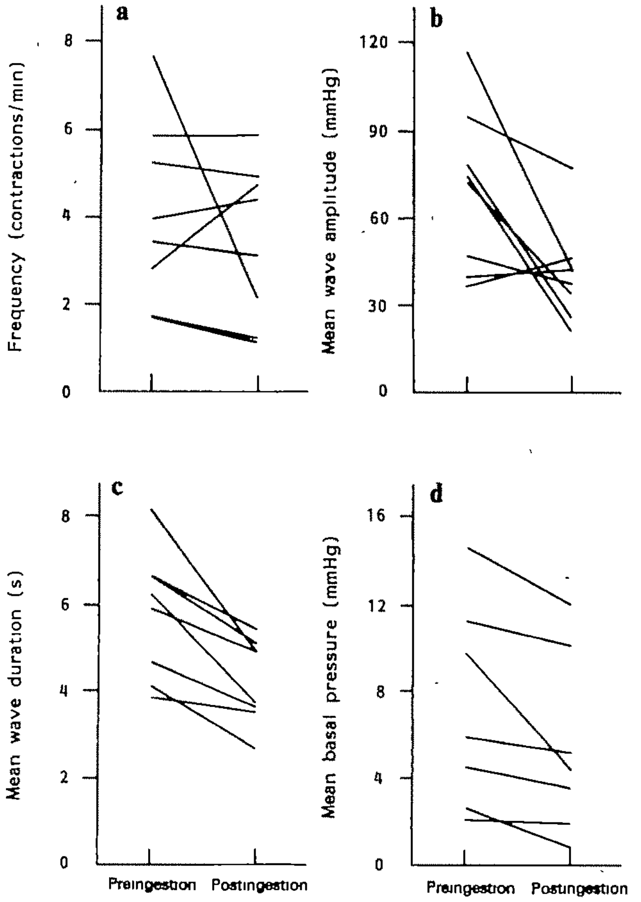

Figure 6 *Comparison of sphincter of Oddi wave* **a** *frequency,* **b** *amplitude,* **c** *duration and* **d** *basal pressure, 10 min before* versus *20 min after food ingestion in eight patients (except for basal pressure where baseline drift excluded data from one patient from analysis). Ingestion of food produced a significant fall in sphincter of Oddi amplitude, duration and basal pressure. There was no change in sphincter of Oddi frequency*

rhythmic contractile activity corresponding to phase III duodenal activity
3. The sphincter of Oddi's rapid contractile activity usually preceded duodenal phase III activity and was of longer duration. Furthermore, the contractile frequency was different in the sphincter of Oddi when compared with the duodenum
4. The sphincter of Oddi basal pressure remained constant throughout the interdigestive cycle except for a brief period during duodenal phase III and early duodenal phase IV
5. After feeding, there was a fall in sphincter of Oddi basal pressure and sphincter of Oddi wave amplitude and duration. There was no change in sphincter of Oddi frequency. Conversely, the duodenum demonstrated a fed pattern with an increase in frequency.

In order to evaluate the interdigestive and fed activity of the sphincter of Oddi in man, patients with indwelling T tubes were used to provide access to the sphincter of Oddi. Neither the T tube modification nor the manometric studies adversely influenced the patients' clinical progress. All of the patients studied were recovering from surgery on the gallbladder and bile duct for stones, hence cannot be considered as having a normal biliary system. Studies in animals[16,17] have shown that cholecystectomy does not alter resting sphincter of Oddi activity. Particular attention was given to avoiding injury to the sphincter of Oddi during surgery, however any effect of the stones in modifying the motility cannot be excluded[13,18]. Furthermore, an effect of the T tube on sphincter of Oddi motility cannot be excluded. In previous studies[13,18] we had shown that stones in the gallbladder or bile duct were associated with an excess of retrograde sphincter of Oddi contractions but no other motility alterations. The significance of these findings with respect to gallstone formation is unknown. In this current study we did not evaluate sphincter of Oddi sequences. However, as best as could be assessed clinically and radiologically, the sphincter of Oddi was otherwise functioning normally.

Particular care was exercised in minimally stimulating the gastrointestinal tract and sphincter of Oddi before and during these studies. We were also conscious of the possibility of producing the complications of pancreatitis and cholangitis due to the placement of the manometry catheter across the sphincter of Oddi and perfusion of the biliopancreatic system; hence the studies were limited to a period of less than 5 h and the system was left open to prevent a pressure build-up. The additional radiation dosage precluded the use of radiological screening to monitor the catheter position continuously.

Prolonged manometric recording during the interdigestive period confirmed findings from a previous study in man[19,20] demonstrating the independence of sphincter of Oddi phasic contractions from duodenal contractions. Unlike duodenal contractions, the sphincter of Oddi contractions were omnipresent and the sphincter of Oddi did not exhibit a period of quiescence. This finding is similar to that reported in the opossum[21,22] and dog[3] and suggests that the sphincter of Oddi contractions may have an important role in maintaining the patency of the bile duct and pancreatic duct by continually expelling fluid from within the sphincter of Oddi segment.

The timing of the sphincter of Oddi activity fronts just before the duodenal phase III has been reported in the opossum[21]. In separate studies we measured human gallbladder volume in relation to duodenal activity and demonstrated that the gallbladder also begins partial emptying just before duodenal phase III activity[23]. These observations were supported by other studies in man which showed a rise in bile salt concentration just before duodenal phase III activity[24,25]. The physiological significance of this inter-relationship between gallbladder contraction and the sphincter of Oddi and duodenal activity fronts is unclear. The difference in timing may reflect the anatomical relationship and have no important physiological connotations. On the other hand, because the gallbladder and sphincter of Oddi activity precedes duodenal phase III, it raises the possibility that an initiator of phase III activity may be sited in the biliary tract. Teleologically it may be argued that an increase in sphincter of Oddi activity should precede duodenal phase III to guard against any reflux of duodenal contents into the bile duct or pancreatic duct which may be generated by the increased activity in the duodenum.

The sphincter of Oddi basal pressure also increased during phase III and into phase IV, which would further guard against reflux during this period of increased duodenal activity. The low sphincter of Oddi basal pressure demonstrated only minor fluctuations throughout the remaining interdigestive cycle, suggesting that normally the sphincter of Oddi does not generate a large resistance to the flow of bile from the duct into the duodenum.

Presentation of food to the patients did not influence sphincter of Oddi or duodenal motility significantly. Our failure to detect a significant change may be because the liquid meal was given only 10 min after presentation of food. If we had waited for a longer period, changes attributable to a cephalic stimulus alone might have been detected.

A nutritionally balanced liquid meal was chosen as the meal stimulus in order to ensure rapid transit from the stomach into the duodenum. We did not objectively monitor the transit of the liquid meal into the duodenum, however we have no cause to believe that any of our subjects suffered from gastric emptying disorders. After the ingestion of the liquid meal, the sphincter of Oddi demonstrated a decrease in wave amplitude with a corresponding decrease in wave duration and a fall in basal pressure. There was no effect on sphincter of Oddi contraction frequency. These changes in activity result, however, from the combination of both the cephalic stimulus and the meal stimulus. The cephalic-induced component of these responses is the subject of further investigation. Other studies in man[7,26] and dogs[27] have shown an increase in flow and corresponding decrease in resistance to flow across the sphincter of Oddi after a meal. Our results suggest that the decrease in resistance across the sphincter of Oddi is produced by this fall in basal pressure and decreased wave amplitude and duration and that the increased flow is facilitated by a passive decrease in resistance and not an active pumping action of the sphincter. This response is different from that seen in opossums, where the response of the sphincter of Oddi to food is a pronounced increase in contractile activity[21,22].

The mechanisms by which these stimuli produced changes in sphincter of Oddi motility were not addressed in this study. Previous studies have shown that an intravenous bolus injection of cholecystokinin octapeptide produced inhibition of sphincter of Oddi phasic contractions[28–31]. The assumption was made that a meal would act on the sphincter of Oddi via the release of endogenous cholecystokinin[32] to produce inhibition of the phasic contractions. This assumption has not been substantiated by our study. Although the amplitude of the phasic contractions has been reduced, total inhibition of the contractions was only transiently recorded in three of our eight subjects. The differences in these observations may be due to the simultaneous release of other hormones after the meal and the interplay between hormonal and neuronal effects on the sphincter of Oddi. Furthermore, the doses of cholecystokinin octapeptide that were used in previous studies may reflect a pharmacological response of the sphincter of Oddi to the stimulus, and not its physiological action.

The results of this study have demonstrated that sphincter of Oddi contractions exhibit a cyclical pattern during the interdigestive cycle. However, unlike the rest of the gastrointestinal tract[33–36], there is no quiescent phase, which may reflect the unique and vital function of the sphincter of Oddi in controlling flow across a very busy anatomical junction. The onset of the sphincter of Oddi activity front precedes that in the duodenum and the sphincter of Oddi basal pressure subsequently increases, suggesting that the sphincter of Oddi inhibits reflux of intestinal contents into the biliary tree during this period of increased duodenal activity. After a meal, passive flow may be enhanced by a fall in the sphincter of Oddi basal pressure and a decrease in the wave amplitude and duration.

Dr S. Kitano

Fifty cirrhotic Japanese patients with oesophageal varices underwent sclerotherapy in a prospective randomized trial carried out to examine the effects of human thrombin given concomitantly with the sclerosant 5 per cent ethanolamine oleate. The two groups (25 patients each) were comparable with regard to size of the oesophageal varices, and the aetiology and severity of the liver disease. Twenty-five patients, 13 and 12 in the thrombin + and − groups, respectively, had at least one episode of variceal bleeding. The remaining 25 were given prophylactic injections. There was a significantly lower rate of occurrence of bleeding from injection sites when the injection needle was removed at the initial session of sclerotherapy in the thrombin + group, where human thrombin was injected (0·2–0·3 ml, 100–150 units per injection) just before removal of the injection needle. Endoscopy at 1 week after the initial session showed a significantly ($P<0{\cdot}05$) *higher rate of disappearance of red colour signs on varices in the thrombin + group (96 per cent) than in the thrombin − group (72 per cent). Fibrin degradation product E-fraction (FDP-E) values increased 1 h, 1 day and 6 days after the initial session of sclerotherapy in the two groups. The rate of increase in FDP-E values 1 h after sclerotherapy was significantly larger* ($P<0{\cdot}001$) *in the thrombin + than in the thrombin − group. There was no clinical sign of disseminated intravascular coagulation. Administration of human thrombin plus a sclerosant seems to be useful and efficacious, especially for patients with huge oesophageal varices.*

Keywords: Injection sclerotherapy, oesophageal varices, 5 per cent ethanolamine oleate, human thrombin

Various compounds have been used[1–5] for endoscopic injection sclerotherapy. Bleeding from injection sites is still one possible major cause of the failure of this treatment because precise injection of the sclerosant may not be attained when the bleeding makes for poor visualization of the varices[6].

A low dose of human thrombin has been injected intravariceally or submucosally to prevent massive bleeding from the puncture points[7,8]; however, the safety of this procedure has not been established.

In the present prospective randomized trial, we compared the findings when we injected 5 per cent ethanolamine oleate plus human thrombin, with 5 per cent ethanolamine oleate only, for patients with oesophageal varices. Particular attention was given to blood coagulability and to the clinical features.

Patients and methods

From December 1987 to April 1988, 50 cirrhotic Japanese patients with histologically proved cirrhosis of the liver (mainly non-alcoholic), portal hypertension and oesophageal varices were randomly allocated to either the thrombin + or the thrombin − group. Randomization was done by flipping a coin for the first of each pair of patients. With informed consent, 25 were given endoscopic injection sclerotherapy, using human thrombin just after each intravascular injection of the sclerosant 5 per cent ethanolamine oleate; for the remaining 25, thrombin was not used. Eight patients presenting acute variceal bleeding during the same period were not included in this study.

Patients with blue varices of a moderate or huge size (F2, F3) and showing either red whale marking (RWM + +, + + +), cherry red spot (CRS + +, + + +) or haematocystic spot (HCS +), were given prophylactic injections according to our criteria[9]. On entering the trial, the patients were classified into grades A, B or C[10].

Treatment was performed using a GIF Q10 Olympus (Olympus Optical Company, Tokyo, Japan) endoscope; the patients were sedated with 5–10 mg diazepam and 15–30 mg pentazocine. Intravariceal injection was initiated approximately 2 cm above the Z-line and was continued in a cranial direction with the free-hand technique, using 5 per cent ethanolamine oleate. The initial two sessions of endoscopic injection sclerotherapy were performed by the principal author (S.K.).

In the thrombin − group, 1·5–2 ml 5 per cent ethanolamine oleate were given per injection; a total of 12–18 ml was injected at the initial session. In the thrombin + group, 0·2–0·3 ml (500 units/ml) human thrombin (Green Cross, Osaka, Japan) was injected intravariceally and submucosally when withdrawing the injection needle and just after giving the 5 per cent ethanolamine oleate injection, in order to prevent massive bleeding from the puncture points.

Repeated sclerotherapy at approximately 1-week intervals was performed until all the oesophageal varices had been eradicated. Sclerotherapy was not repeated when endoscopic findings of the varices showed no definite improvement from the previous session, that is, obliteration of the varices, ulcers or a superficial circumferential ulcer in the lower oesophagus.

The endoscopic features at the first two sessions were recorded. Severity of postinjection bleeding per injection was graded as: jet-like bleeding, continuous bleeding requiring further injections, and no continuous bleeding (ceased within 30 s) from injection sites. At least four of the present authors attended all sessions of sclerotherapy and graded bleeding from the injection sites by observing the endoscopic appearance of the varices through a medical television system (Medical TV System, Model OTV-F2, Olympus Optical Company). To measure blood loss during the procedure, we used a 100-ml glass chamber between the fibreoptic endoscope and the main suction chamber. The blood in the oesophagus was collected through an endoscopic suction channel during the procedure. When there was a small amount of bleeding, blood loss was estimated by the blood concentration in the chamber after flushing with 20 ml saline. The volume of 5 per cent

Time for sclerotherapy (min)	11·6 (1·4)	15·9 (1·8)	<0·001
Blood loss (>20 ml)	0/25 (0%)	9/25 (36%)	<0·005

Values are mean (s.d.); statistical analyses were by Student's t test except for blood loss (χ^2 test); n.s., not significant; EO, ethanolamine oleate

ethanolamine oleate and human thrombin solution injected, the time taken and the blood loss during the procedure were recorded for subsequent assessment of complications and efficacy. Particular attention was directed to coagulability status after the initial session of sclerotherapy The platelet count, prothrombin time, partial thromboplastin time and fibrinogen and fibrin degradation product E-fraction (FDP-E) of each patient were analysed in the early morning before sclerotherapy. Repeat measurements of haematological parameters were made 1 h, 1 day and 6 days after the completion of the initial session.

The variables of interest were compared using either the χ^2 test or Student's t test.

Results

Characteristics of the two groups

Table 1 shows the clinical characteristics of the patients studied. The two groups were well matched for all variables. Thirteen patients in the thrombin + group and 12 in the thrombin − group were treated, on an elective basis, 3–28 days after their latest episodes of variceal bleeding. Prophylactic injection was given to 12 patients in the thrombin + and 13 in the thrombin − group, as the endoscopic findings showed a risk of bleeding. There were eight patients with a concomitant hepatoma (four in each group), lesions which were not resectable for functional and/or anatomical reasons (poor liver function, huge or multiple hepatomas).

Endoscopic features at the initial session (Table 2)

Jet-like bleeding from an injection site occurred in 19 per cent of cases with a mean of 9·6 injections in the thrombin − group, but this type of bleeding never occurred in the thrombin + group. The difference was statistically significant ($P<0·001$). There was also a significant difference ($P<0·001$) in the frequency of bleeding-free injections between the two groups, 94 *versus* 46 per cent in the thrombin + and thrombin − groups, respectively.

Time and blood loss (>20 ml) during the procedure were significantly shorter in the thrombin + group than in the thrombin − group, and the total volume of 5 per cent ethanolamine oleate injected was comparable in the two groups. There were nine patients who lost more than 20 ml of blood during the procedure in the thrombin − group, whereas there were none in the thrombin + group, the difference being statistically significant ($P<0·005$). In patients with F3 (huge and nodular form) varices, there was a higher rate (seven of 12, 58 per cent) of bleeding from injection sites than in the patients with F2 (moderate and rosary) varices (two of 13, 15 per cent).

Endoscopic findings 1 week after the initial session

Table 3 shows endoscopic findings 1 week after sclerotherapy. In 24 of the 25 patients in the thrombin + group, the oesophageal mucosa over the varices where the sclerosant had been injected was thick and swollen, presumably the effect of thrombosis and inflammation resulting in disappearance of red colour signs on varices. In the thrombin − group, the oesophageal varices were endoscopically patent and showed a considerable degree of red colour signs in seven of 25 patients, the difference being statistically significant (96 *vesus* 72 per cent, $P<0·05$). In accordance with endoscopic findings, continuous bleeding from injection sites requiring further injection at the second session occurred more frequently in the thrombin − group (30 per cent of an average of 9·2 injections) than in the thrombin + group (9 per cent of an aveage of 8·6 injections), the difference being statistically significant ($P<0·05$). Occurrence of oesophageal ulceration 1 week after the initial session was significantly ($P<0·05$) more frequent in the thrombin − group than in the thrombin + group.

Number of sessions, period, and volume of the sclerosant

The number of sessions, weeks of treatment and total volume of 5 per cent ethanolamine oleate for eradication of oesophageal varices did not differ between the two groups, as shown in *Table 4*. At the late stage of repeated injections, the residual mucosa was partly necrotized and eliminated with submucosal spread of the sclerosant and the mucosa remained, despite the

FDP-E level (ng/ml)	Thrombin + group ($n=25$)		Thrombin − group ($n=25$)	
	Before	After	Before	After
0–100	16	0	17	3
100–500	9	7	8	22
>500	0	18	0	0
Mean (s.d.)	103·3 (82·7)	1982·3* (1638·7)	92·5 (78·8)	214·8* (132·1)

FDP-E, fibrin degradation product E-fraction; * $P<0·001$ compared with the values before sclerotherapy (Student's *t* test). the increase was significantly ($P<0·001$) larger in the thrombin + group

administration of a sufficient volume. The rate of attainment of a superficial circumferential ulcer formation (our proposed end-point) in the lower oesophagus[11] did not differ between the two groups, 64 *versus* 56 per cent in the thrombin + and − groups, respectively.

No patient died during the course of repeated injections and all could be given a sufficient number of sessions. One patient in each group died of a concomitant hepatoma 4 and 5 months after the initiation of therapy. At the time of writing, 24 patients in each group are living with no episode of bleeding.

Alteration of parameters of the coagulating system

There was a significant increase in FDP-E 1 day after the initial session in both groups (*Table 5*), while the other parameters showed no significant increase. The value of FDP-E remained significantly high for the following week ($P<0·001$). The increase in FDP-E was significantly ($P<0·001$) larger in the thrombin + group than in the thrombin − group 1 h after completion of the first session: 19·8 × *versus* 2·4 ×, compared with the pre-injection values (*Table 6*). Four patients of the thrombin + group showed a markedly high value in FDP-E level (more than 4000 ng/ml), without presenting clinical signs of bleeding tendency or intravascular coagulation throughout the course of repeated sclerotherapy.

Complications

There were no major complications, such as oesophageal perforation or shock, directly related to the procedure or injection of a low dose of human thrombin, except for the previously mentioned haematological abnormalities. Oesophageal bleeding did not occur during the entire course of repeated injections. There was no statistically significant difference in the frequency of minor complications between the two groups: pain requiring opiate analgesics in 8 per cent of the thrombin + and 12 per cent of the thrombin − group; pyrexia (>38°C) in 32 and 40 per cent respectively; and pleural effusion on chest X-ray in 40 and 48 per cent, respectively. Oesophageal stricture which required bougienage occurred in three and four patients of the thrombin + and − groups, respectively.

Discussion

Since the first report by Crafoord and Freckner[1], various agents have been used to sclerose oesophageal varices. In our prospective randomized clinical trials[12,13], 5 per cent ethanolamine oleate was found to be superior to 1 per cent polidocanol or 2 per cent sodium tetradecyl sulphate. In canine models[14] with portal hypertension, Jensen *et al.* found that 5 per cent ethanolamine oleate proved to be the most efficacious single agent for sclerosing oesophageal varices, with a low rate of occurrence of oesophageal ulceration after the injection.

Many workers performed endoscopic injection sclerotherapy with a free-hand technique, under conditions of topical anaesthesia. However, recurrent bleeding or continuous bleeding from the injection site is still a major cause of failure of sclerotherapy, especially at the very early stage[5,6,15].

Some investigators favoured the use of a low dose of human thrombin together with other sclerosants[7,8,16], the objective being to prevent massive acute bleeding and to obtain accurate visualization. In the present study, we confirmed that use of a low dose of human thrombin makes injection sclerotherapy an easier technique to perform as the view of the varices is not obscured by bleeding.

Gardner and Brooks[7] reported no definite evidence of disseminated intravascular coagulation after intravariceal injection of 5 per cent sodium morrhuate and a solution containing thrombin. Bernardie *et al.*[17] suggested that 5 per cent ethanolamine oleate caused no significant deterioration of coagulation, even in patients with an abnormal coagulative function, and that temporary activation of the coagulating process might be self-limiting and confined to the laboratory level. In our present study, the serum level of FDP-E was higher than the normal limit for at least the first week in all patients given an injection of 5 per cent ethanolamine oleate, even after the other parameters had recovered to the pre-sclerotherapy level. The additional use of human thrombin after each injection of 5 per cent ethanolamine oleate caused a significantly higher increase in the FDP-E level than did 5 per cent ethanolamine oleate alone Much more attention should be directed to this higher FDP-E level increase

(>4000 ng/ml) seen in four patients injected with human thrombin (750–1250 units) intravariceally and submucosally. These high values suggest that cirrhotic patients are in a predisseminated intravascular coagulation state even before injection and that such a state may readily occur after intravariceal injection of human thrombin, even though sclerotherapy can be performed with little bleeding.

Larger varices tend to bleed more during the procedure To prevent active and massive bleeding from the injection sites, low dose human thrombin is an effective agent. Nevertheless, injection of 5 per cent ethanolamine oleate led to deterioration in the coagulation system and the additional use of human thrombin caused a further deterioration of the coagulation system in patients with liver cirrhosis.

On the basis of this trial, we recommend that low dose human thrombin is used, with the free-hand technique, to prevent bleeding from injection sites and to obtain a complete thrombosis of variceal channels in patients with large oesophageal varices, otherwise active bleeding may occur just after the intravenous injection of the sclerosant. Close follow-up is necessary to predict and prevent the occurrence of true disseminated intravascular coagulation.

Injection sclerotherapy for acutely bleeding oesophageal varices has been used in Belfast since 1958. However, a chronic injection sclerotherapy programme with rigid oesophagoscopy under general anaesthesia commenced only in 1979. So far, 82 patients have entered the programme; 57 patients had already received 73 acute injections before commencing chronic sclerotherapy. Subsequently, the 82 patients received 221 chronic injections plus a further 29 acute injections for rebleeding episodes which occurred during the programme. There were 24 Child's grade A patients, 23 B and 35 C; 48 per cent had alcoholic cirrhosis. Forty-eight patients achieved variceal obliteration with a mean of four injections. During the programme 24 patients experienced 42 acute bleeds. There were only two bleeding episodes within 1 week of a chronic injection and eight within 4 weeks. In the 8-year period there have been four early deaths. One occurred 17 days after a chronic injection and three followed acute injections required for rebleeding during the programme. There were 21 late deaths, mostly due to progressive liver failure, and none from rebleeding. We conclude that chronic injection sclerotherapy using rigid oesophagoscopy under general anaesthesia is both safe and effective.

Keywords: Injection sclerotherapy, oesophageal varices, rigid oesophagoscopy, general anaesthesia

The first report[1] of the use of injection sclerotherapy for bleeding oesophageal varices was published in 1939. Injection sclerotherapy for acutely bleeding oesophageal varices has been used in Belfast[2] since 1958. A previous report from this unit reviewed 25 years of experience of injection sclerotherapy for acute bleeding from oesophageal varices[3]. This gave a control rate of 91·4 per cent with a mortality rate of 14·9 per cent. After the acute episode, some regimen of definitive therapy is necessary to prevent recurrent variceal haemorrhage. Medical therapy using propranolol[4–7], shunt surgery[8–12], oesophageal transection[13,14] and chronic injection sclerotherapy[15–18] have all been used. A chronic injection programme commenced in Belfast in 1979 and this paper reviews our results Most authorities advocate the use of a flexible endoscope with or without an oversheath for chronic injection. In our programme, rigid oesophagoscopy and general anaesthesia were used for both acute and chronic injections. This resulted in minimal operative mortality and morbidity and a high rate of variceal obliteration.

Patients and methods

Patients

Eighty-two patients entered the programme between January 1979 and October 1987 There were 39 men and 43 women in the series. The age ranged from 17 to 83 years with a mean of 52·9 years Severity of liver disease upon entering the programme was assessed using Pugh's modification of Child's grading. There were 24 grade A (30 per cent), 23 grade B (28 per cent) and 35 grade C patients (42 per cent).

Most of our patients selected for chronic sclerotherapy were those considered unfit or unsuitable for surgery. However, 11 good-risk patients were entered as part of a random group in a multicentre chronic injection sclerotherapy trial. Another five good-risk patients were deliberately selected because their underlying pathology was extrahepatic venous obstruction. No patient was rejected from the programme because of poor liver function.

The aetiology of the portal hypertension is shown in *Table 1*. Patients without evidence of alcohol abuse, other causes of intrahepatic portal hypertension or extrahepatic venous obstruction were included in the cryptogenic group. Just over 50 per cent of our alcoholic cirrhotics became total abstainers

Injection technique

Anaesthesia is induced with thiopentone and paralysis achieved with suxamethonium Maintenance of anaesthesia is by 70 per cent nitrous oxide with oxygen or isoflurane.

The 50-cm wide bore rigid Negus oesophagoscope and long Roberts needle are used. Occasionally the narrower instrument is employed for technical reasons. From 2 to 4 ml of ethanolamine oleate are injected intravariceally into each varix Only the varices in the distal 5 cm of the oesophagus are injected. The oesophagoscope is rotated to compress the previous injection site while injecting a further varix. Postinjection tamponade was not used in any patient

Results

The 82 patients received a total of 323 injections of which 221 were chronic and 102 acute. Of the acute injections, 73 had been given to 57 patients before commencing the chronic injection programme; the other 29 were for acute bleeding during the programme. Although all 82 patients had bled before entering the programme, 25 had not required emergency sclerotherapy

Treatment regimen

Chronic injection sclerotherapy was the only treatment used in 55 of our 82 cases. Seven patients left the programme and underwent an elective oesophageal transection. Secondary chronic injection sclerotherapy was required for variceal recurrence in a further 20 patients who had had prior transection (18 patients) or shunt (two patients).

Variceal obliteration

Of the 82 patients entering the programme, 48 have so far achieved variceal obliteration. Of these, 34 are still alive and 14 have died, mostly from progressive liver failure. This leaves 34 patients who have not achieved variceal obliteration: 11 died before obliteration was considered to have been achieved, and 23 are still alive, currently in our ongoing programme, and should soon achieve obliteration of their varices. The 48 patients with obliterated varices required a total of 192 injections. This ranged from one to ten, and the mean number of injections required was 4·0. After variceal obliteration, endoscopic review using the flexible instrument is performed annually.

Variceal bleeding

In the very early stages of our programme, there was no rigid schedule of timing of chronic injections. Consequently, some patients received their first chronic injection more than 1 month after their initial acute injection. The gap between chronic injections also varied, and was occasionally longer than 3 months. We soon adopted a schedule of chronic injection 1 month after the initial acute injection and then repeated at monthly intervals. There were a total of 42 episodes of variceal rebleeding in 24 patients after commencing the programme. In five of these patients the bleeding site was non-variceal. These included hiatal hernias with oesophagitis, gastric erosions, prepyloric ulceration and duodenal erosion. In the 19 patients bleeding from varices, 29 of the bleeding episodes required acute injection sclerotherapy. Two episodes occurred within 1 week of a chronic injection, three by 2 weeks, three by 4 weeks, thirteen within 12 weeks, and the remainder after this period. The incidence of rebleeding has decreased since patients began routine monthly chronic injections.

Complications

The 82 patients received a total of 221 chronic injections under general anaesthesia. One Child's grade C patient died from progressive liver failure after a chronic injection. One patient had a minor cervical oesophageal leak which settled with conservative management. One of the advantages of a general anaesthetic is the safe airway, and there was only one case of aspiration pneumonitis. There were no episodes of unsuccessful intubation and no morbidity or mortality could be attributed to the general anaesthetic. Oesophageal ulceration was noted in only two patients and none of the 82 patients subsequently developed an oesophageal stricture. In the first 48 h, a pyrexia of up to 38°C occurred in about 20 per cent of patients. Mild retrosternal pain was experienced by about 35 per cent of patients.

Mortality

In the 8-year period under review there was a total of 25 deaths in the 82 patients (*Table 2*). Four of these deaths occurred in hospital, related to injection sclerotherapy. As mentioned earlier, one hospital death occurred 17 days after a chronic injection and was due to progressive liver failure in a Child's C patient. The other three hospital deaths (two Child's B, one Child's C) occurred at 12, 20 and 25 days respectively, after acute sclerotherapy for rebleeding episodes. These deaths were all due to liver failure.

Discussion

The prevention of recurrent haemorrhage from oesophageal varices is a controversial topic. Proposed regimens include medical therapy, injection sclerotherapy and operative treatment such as shunting or oesophageal transection.

Chronic injection sclerotherapy has received increasing attention in recent years. The combined results of three prospective controlled studies involving 173 patients showed that a chronic injection programme is effective[15–17]. The number of patients rebleeding fell from 67 to 52 per cent and the number of rebleeding episodes was almost halved. Terblanche showed that survival in a group undergoing chronic injection was unchanged compared with a control group[16]. This control group, however, did receive acute injections for rebleeding episodes. The rate of admission for rebleeding was decreased from 77 to 58 per cent, making life less traumatic for both patients and surgeon. In this series only 29 per cent of the patients experienced any bleeding episodes during the programme and not all of these were due to varices.

There is controversy over the best injection site for sclerotherapy, the correct timing and the most suitable instrument. Intravariceal injection produces a more rapid obliteration of varices than the paravariceal route. Rose *et al.*, comparing the two, showed a more rapid reduction in variceal size and a significant reduction in the number of injection sessions required with intravariceal injection[19]. Another study showed that intravariceal sclerotherapy was superior to paravariceal in the control of active variceal bleeding and for total obliteration of varices, but was associated with a higher variceal recurrence rate[20].

The timing of injection has been assessed by the King's College Hospital Group, who found that sclerotherapy performed at intervals of <3 weeks increased the complication rate but resulted in earlier variceal obliteration[21]. Sarin *et al.* found that weekly rather than 3-weekly injections gave both earlier obliteration and decreased rebleeding[22]. They judge the greatly increased incidence of mucosal ulceration with earlier injection to be inconsequential. We feel that a monthly injection regimen permits oedema, mucosal inflammation and any ulceration to resolve before any further injection. In our experience the incidence of rebleeding within the first month of the initial sclerotherapy has been very low – only eight episodes in the whole series.

Rigid oesophagoscopy gives better visualization than flexible oesophagoscopy, permitting more accurate intravariceal injection of lower volumes of sclerosant. Intravariceal injection is aided by the venous distension produced by the rigid instrument. Haemorrhage is controlled by compression, which also traps the sclerosant in the varix, aiding sclerosis. The main disadvantage of rigid oesophagoscopy is said to be the risk of perforation. We had only one minor cervical perforation in 221 chronic injections in our 82 patients. Our method achieved a very low rate of ulceration and no postinjection stenosis. The rate of mucosal ulceration observed in one study was 80 per cent for a weekly injection regimen and 33 per cent for a 3-weekly injection regimen[18]. We noted only two instances of ulceration in 82 patients (2 per cent). This figure is falsely low because of our decreased frequency of endoscopy compared with other series. It may also reflect the value of accurate intravariceal injection and lower volumes of sclerosant. None of our 82 patients subsequently developed an oesophageal stricture. This compares very favourably with stricture rates of 17·6 per cent using 3-weekly flexible endoscopy[15] and 8·5 per cent using weekly flexible endoscopy[22], both under sedation. Howard *et al.*, who employed general anaesthesia but differed from us in using flexible endoscopy[23], had a stricture rate of 16 per cent. Perhaps it is worth noting that in 30 years of injection sclerotherapy with the rigid oesophagoscope we have seen only two minor strictures in over 800 injections in more than 400 patients.

The most controversial aspect of this review is the need to use general anaesthesia for a chronic injection programme using the rigid instrument. However, a general anaesthetic safeguards the airway, prevents aspiration of blood and maintains good oxygenation throughout the procedure. In addition, recovery is quicker than with sedation and many patients prefer to be fully asleep, an important factor in patient compliance. Howard *et al.* also defend the use of general anaesthesia in their large series of 152 children and teenagers with oesophageal varices[23]. The main disadvantage is the extra 24 h required as an in-patient.

Most authorities advocate flexible endoscopy under sedation for chronic sclerotherapy. The Cape Town controlled trial comparing rigid and flexible oesophagoscopy showed no difference in morbidity or mortality[24]. It is accepted that either rigid or flexible endoscopy may be used for a chronic sclerotherapy programme depending on the preference and expertise available. Most importantly, the operator must be proficient in whichever technique is practised. While we do not advocate the routine use of rigid endoscopy, we do defend its use in centres experienced in the technique. Our results show that chronic injection sclerotherapy using rigid oesophagoscopy under general anaesthesia is both safe and effective.

Because of its anatomy, the liver can be divided into two hemilivers suitable for use as two grafts for liver transplantation. The line of division is the main scissure, giving the right hemiliver (segments 5–8) and the left hemiliver (segments 2–4). Segment 1 (caudate lobe) has to be resected. The vessels are divided between the two grafts: the vena cava remains on the right; on the left, the left hepatic vein is sutured into the vena cava of the recipient, which is retained intact. The left graft retains only the left branch of the portal vein, the bile duct and the hepatic artery. The right graft retains the portal trunk, the common bile duct and the right branch of the hepatic artery. This procedure was used for emergency grafting of two patients with fulminant hepatitis when only one donor was available. Both recipients recovered from coma and regained normal liver function. However, both died from causes not specifically related to the operative technique, one from multiple organ failure on the 20th day and the other from diffuse cytomegalovirus infection on the 45th day.

Keywords: Liver transplantation, partial graft, live donor

In 1978, we started a programme of emergency heterotopic liver transplantation for patients with end-stage cirrhosis, using only a portion of the donor liver in order to have room in the abdomen for the transplant[1]. In 1983, the same technique of graft reduction was used in children for orthotopic transplantation[2] and, in 1986, it was used for emergency transplantation for fulminant hepatitis[3]. In this reduced-sized liver, the entire vena cava and the portal pedicle are retained, and vascular and biliary reconstruction are the same as in the usual orthotopic liver transplantation. A partial liver graft[4] (often improperly called a segmental graft) is different in that only some of the branches of the major vessels of the portal pedicle and of the vena cava are used. In this report we describe the use of one donor liver for two orthotopic transplantations by dividing the liver to obtain functional livers for each of two patients with fulminant hepatitis.

Patients and methods

A 45-year-old woman with fulminant hepatitis of indeterminate cause was admitted on 1 May 1988. She was comatose, with inco-ordinate response to nociceptive stimuli (grade III coma). Her biochemical tests showed: serum bilirubin 380 μmol/l, serum alanine aminotransferase 980 units/l, prothrombin 10 per cent of normal, and serum creatinine level 95 μmol/l. The only available donor was in Bern, Switzerland. Biochemical tests on the donor revealed: serum bilirubin 5 μmol/l, serum alanine aminotransferase 42 units/l, γ-glutamyl transpeptidase 400 units/l, and prothrombin 60 per cent of normal. Multiple organs were harvested, with infusion of the kidneys and the liver with University of Wisconsin solution[5]. The weight of the liver was 2·6 kg. As the hepatectomy on the recipient was started, however, a 55-year-old woman with drug-induced fulminant hepatitis was admitted. She was diabetic and had a history of arterial hypertension. On 13 April she had become jaundiced and her serum alanine aminotransferase was 700 units/l. On admission, she was comatose (grade III), anuric and was receiving mechanical ventilation. Her biochemical tests were serum bilirubin 420 μmol/l, serum alanine aminotransferase 420 units/l, prothrombin 12 per cent of normal, and serum creatinine level 350 μmol/l. The preoperative blood cultures and culture of ascitic fluid were positive for *Escherichia coli* and *Enterobacter cloacae*. We decided to modify the surgical procedure to obtain two functional hemigrafts for the two patients.

Technique of division of the liver graft (Figure 1)

After the usual *ex vivo* preparation of the graft, the liver and the hepatic pedicle were divided into two parts. The left hemigraft consisted of the left liver (segments 2–4), the left hepatic duct, the left branch of the portal vein, and the complete hepatic artery from the coeliac axis but without the right branch. The hepatic veins consisted of the left hepatic vein and an accessory middle hepatic vein (with a common opening) with a small cuff of vena cava. The surface of the left hemigraft was covered with a fibrin glue (Tissucol-Immuno Ag, Vienna, Austria).

The caudate lobe of the right hemigraft was resected because it received its portal blood supply from the left portal branch (taken with the left graft). The right hemigraft consisted of the right liver (segments 5–8) with the portal vein in continuity with the right portal branch, with the right branch of the hepatic artery, and with the common bile duct in continuity with the right hepatic duct. The hepatic veins of the right liver consisted of the right and the middle hepatic veins and the vena cava. The cut surface of the hemigraft was covered with fibrin glue. Preparation of the two hemigrafts took 2 h 30 min.

Liver transplantation in the first patient

Because this patient was smaller than the second, she received the left hemigraft. Her liver was removed, conserving the vena cava. The orifices of the left and middle hepatic veins were sutured to the small cuff of the vena cava of the donor with the two hepatic veins. The left portal branch of the hemigraft was sutured to the portal vein of the recipient. After portal revascularization of the graft, the coeliac axis of the graft was sutured to the common hepatic artery of the recipient. Finally, because of the lack of length of the left bile duct, it was anastomosed to a Roux-en-Y loop of jejunum. Flow in the intrahepatic vessels was assessed by Doppler ultrasound. The graft had been ischaemic for 7 h 50 min.

Liver transplantation in the second patient

This transplantation started before the end of the first procedure. Total hepatectomy was accomplished according to the usual technique. The only technical variation concerned the hepatic artery, which was completely dissected to keep its right branch. This branch was sutured to the right hepatic arterial branch of the recipient. The biliary tract was reconstructed by an end-to-end suture of the common bile duct of the graft and of the recipient over a T tube. The graft was ischaemic for 12 h 50 min. The surgical procedure on the two patients lasted 16 h.

Results

Postoperative course of the first patient

The first patient regained consciousness completely 36 h after surgery and was extubated on the second day. On the following days, the liver function tests returned to normal. The patient was discharged from the intensive care unit on the eighth day. The postoperative course was uneventful until the 22nd day, when the patient developed a diffuse cytomegalovirus infection; she died of pneumonitis on the 45th day. At the post-mortem examination, the liver parenchyma appeared homogenous; all the vascular and biliary anastomoses were patent and there was a massive haemorrhagic infiltration of the lungs which was responsible for death.

Postoperative course of the second patient

The haemodynamic condition of the patient remained poor. She was reoperated on for haemoperitoneum on the second day and again on the fifth day. The serum levels of aspartate aminotransferase reached 4600 units/l on the second day, then returned progressively to normal; her prothrombin time returned to 60 per cent of normal on the third postoperative day. She regained consciousness completely but continued to require mechanical ventilation. The postoperative course was complicated by the persistence of renal failure requiring repeated haemodialysis, the development of disseminated intravascular coagulopathy, and sepsis due to *Candida albicans*. The patient died from multiple organ failure on the 20th postoperative day. At the post-mortem examination, the liver parenchyma appeared homogenous; all the vascular and biliary anastomoses were patent.

Discussion

Because we needed to perform two emergency transplantations simultaneously when only a single donor was available, we divided one graft to perform two transplantations. Pichlmayr and his co-workers have recently published a similar report[6], using one liver for an adult, who received the right liver plus segments 1 and 4, and for a child, who received the left lateral surgical sector (segments 2 and 3). Even though both patients discussed in our report died, the causes were not specifically related to the operative technique or failure of the graft. The graft function in the first patient was satisfactory as she regained consciousness completely, with a normal prothrombin level, after the second postoperative day. The graft function in the second patient was more difficult to assess as she was in septic shock before, during and after the surgical procedure. However, despite her poor haemodynamic condition, the graft function was satisfactory, as she regained consciousness completely with disappearance of jaundice and a prothrombin level at 60 per cent of normal after the third postoperative day. The best proof of good function of the two grafts is the fact that the two patients, transplanted in a deep coma, regained complete consciousness immediately after the operation. However, more experience and better results are needed before this technique is applied to indications other than emergency situations.

The anatomy of the liver[7] makes possible the use of one divided liver for two transplants. The line of division of the right and left livers runs between segments 5 and 8 on the right and segment 4 on the left. It was preferable to excise the caudate lobe (segment 1), which receives its portal and arterial branches mainly from the left portal pedicle and is drained by small hepatic veins going directly to the vena cava. In our operation, because the left lobe (segments 2 and 3) seemed to be small, the quadrate lobe (segment 4) had to be conserved. Conservation was possible by the presence of an accessory middle hepatic vein for the quadrate lobe[7]. The division of the portal vein and the biliary tree presented no difficulty: the left branches of these two structures being longer than the right, it was better to use them and to keep the portal trunk and the common bile duct in continuity with the right hemigraft. The frequent anatomical variations of the hepatic artery necessitated its division. Although it would have been preferable to perform coeliac arteriography, the anatomy of the portal branches and of the arteries can be studied *ex vivo* by exploring the vessels with a probe. Intraoperative ultrasound, so helpful in studying the anatomical variation of the vessels, could not be applied here because of the presence of the preservation solution and the small bubbles that it contained.

The use of the University of Wisconsin solution makes the procedure easier and more reliable. The hepatic graft has a softer consistency when it is infused with University of Wisconsin solution than with Collins solution, making division of the liver easier. Also, use of the University of Wisconsin solution permits prolonged ischaemic time[5].

The present procedure is an improvement when compared with the reduced-sized graft we described previously, where the remaining liver could not be used for grafting. The 'one for two' procedure and the University of Wisconsin solution should open new possibilities in liver transplantation. For instance, if an emergency liver transplantation is performed with a partial liver graft, the second liver could be used for a patient on the waiting list, chosen according to the anatomical features of the remaining hemigraft. The left hemigraft could be used, preferably in a child (if necessary, reduced to segments 2 and

3 by removing the quadrate lobe), and the larger right hemigraft for an adult. In any case, as it is feasible to use small grafts in adults, one liver could be used for two transplants in order to overcome the shortage of liver grafts.

Another consequence of this technique is the possibility of using a live donor. In this situation, the liver graft would be a partial graft, as we used in our first patient. The only technical difference would pertain to the hepatic artery; however, preoperative angiography could allow one to take only a branch of the hepatic artery. Currently, the only possibly acceptable indication for the use of a live donor for liver grafting would be encountered in a patient dying from fulminant hepatic failure with no other donor available.

Acknowledgements

We are indebted to Dr J. Bernuau and Dr J. P. Benhamou (Hôpital Beaujon, Clichy) for referring the patients to us, to Dr Y. Lerut (Department of Surgery, Inselspital, Bern) for his assistance with the donor and to Dr R. Malt and Dr T. Leese for reviewing the manuscript.

Timing of strangulation in adult hernias

G. P. McEntee, A. O'Carroll, B. Mooney, T. J. Egan and P. V. Delaney

Department of Surgery, Regional Hospital, Dooradoyle, Limerick, Ireland

Correspondence to:
Mr G P. McEntee, Mayo Clinic, Rochester, Minnesota, USA

This retrospective study aimed to determine why the incidence of strangulated hernias in adults remains high. Seventy-nine patients presented with clinical evidence of hernia strangulation which required urgent surgery during the period 1979–87. Forty-six patients (58 per cent) had noted a hernia present for at least 1 month before strangulation: 18 (23 per cent) had not reported it to their family doctor, 19 (24 per cent) were known by family practitioners or non-surgical medical personnel to have a hernia but had not been referred for surgical opinion, and nine (11 per cent) had been previously assessed surgically with a view to elective repair. Of these nine, five were considered unfit, three were on waiting lists for operation and one had refused surgery. Thirty-two patients (40 per cent) presented primarily with strangulation within days of developing a hernia. The duration of hernia before strangulation in one patient was unknown. Although an unavoidable number of patients will continue to present with strangulation within days of developing a hernia, the overall incidence could be significantly reduced by greater public awareness of the risks of hernia strangulation and by a policy of immediate patient referral and prompt elective repair.

Keywords: Hernia, strangulation, timing, surgery

Despite universal acceptance of the value of elective hernia repair[1], the number of patients presenting with strangulation remains high[2–3]. It has recently been suggested that many of those patients who present with strangulation are elderly and are on waiting lists for hernia repair but surgery is delayed or denied them because surgeons and practitioners are exercising a selective policy in favour of younger patients with fewer operative risk factors[3]. This retrospective study analyses the spectrum of strangulated hernias in adults and focuses particular attention on the duration and management of such hernias before strangulation.

Patients and methods

Seventy-nine adult patients (over 20 years of age) who required emergency surgery for suspected strangulated hernia during the period 1979–87 are included in the study Age, sex, site of hernia, coexistent medical illness, operative procedure performed and duration of postoperative stay were recorded. The duration of the hernia before strangulation and any previous hospital admissions during which the hernia had been noted were also recorded Previous visits by the patient to the family practitioner regarding the hernia or during which the hernia was noted were recorded from the case notes or the practitioner concerned

The hernia sites included: 37 femoral (21 right sided), 33 indirect inguinal (19 right sided), five paraumbilical, two incisional, two epigastric and one obturator. One patient developed a strangulated right femoral hernia followed 1 month later by a strangulated femoral hernia on the other side.

Results

Age and sex distribution are outlined in *Figure 1*. The peak incidence for strangulation occurred in the seventh decade of life

The history of presence of a hernia before strangulation is outlined in *Table 1*. Forty-six patients (58 per cent) had noticed a hernia present for at least 1 month before strangulation: 18 (23 per cent) had not reported it to their family doctor (12 inguinal, four femoral, one epigastric, one paraumbilical), ten (13 per cent) were noted to have a hernia by the family doctor and were treated conservatively (five inguinal, four femoral, one incisional), nine (11 per cent) were noted to have a hernia during previous non-surgical hospital admissions and were treated conservatively (five inguinal, three femoral, one epigastric), while nine (11 per cent) had previously been assessed by surgeons with a view to hernia repair (three inguinal, three femoral, two paraumbilical, one incisional). Of the last nine patients, five were considered unfit for elective repair, three were on waiting lists for operation and one had refused surgery. Thirty-two patients (40 per cent) developed strangulation within 7 days of noticing the hernia (23 femoral, eight inguinal, two paraumbilical) One patient referred to above developed a strangulated left femoral hernia within 1 month of repair of the right side. The duration of hernia in one 90-year-old woman who presented with a strangulated obturator hernia was unknown.

Although femoral hernias (23) were more likely than inguinal (eight) to strangulate within 7 days of developing ($P < 0.01$), 14 femoral hernias had been present for at least 1 month before strangulation.

ASA, American Society of Anesthesiologists

The general condition of the 28 patients whose hernia had been noted previously by medical personnel (family doctor, non-surgical hospital personnel or surgeons) but who had not been operated on is expressed using the American Society of Anesthesiologists (ASA) grading system[5] and is detailed in *Table 2*. Six otherwise healthy patients (ASA I: three inguinal, two femoral, one incisional), one patient with rheumatoid arthritis (ASA II) and 12 patients with other life-threatening conditions (ASA III: six inguinal, five femoral, one epigastric) had not been referred for surgical assessment. Of the nine patients who had been assessed surgically, one patient (ASA I) had refused surgery and five were considered unfit (two inguinal, two femoral, one paraumbilical), the reasons being poor general condition (ASA III) in four patients and gross obesity in one patient with a paraumbilical hernia Three patients had been on the waiting list for elective repair, one for 9 months and two for at least 2 years. The reason why the last two had not undergone repair is unclear. The underlying pathology in the 17 patients who were considered 'high risk' (ASA III) included, either alone or in combination, chronic obstructive airways disease (12), congestive cardiac failure (nine), hypertension (five), ischaemic heart disease (four) and cerebrovascular disease (three).

Bowel resection was required in 13 patients (ten femoral, three inguinal), eight of whom developed strangulation within days of the hernia appearing. Seven patients died during the same hospital admission (hospital mortality rate 9 per cent). The causes of death included bronchopneumonia (three), cerebrovascular accident (one), renal failure (one), metastatic carcinoma (one) and intra-abdominal sepsis in a 47-year-old patient who required bowel resection for a strangulated femoral hernia. Three of the deaths occurred in the group of 13 patients who required bowel resection. The median postoperative hospital stay was 9 days (range 4–56 days), with 33 patients in hospital for less than 7 days, 25 for 7–14 days and nine for 14 days or more. Duration of postoperative stay was unrecorded in five patients.

Discussion

Strangulated hernias in this and other recent series[2–4,6] are associated with a mortality rate of approximatly 10 per cent and a significant morbidity in terms of postoperative complications and duration of postoperative hospital stay[2–4]. Mortality and morbidity have been attributed not only to patient factors, such as bowel strangulation which requires resection[2,3] or coexistent medical illnesses[2], but also to poor operative technique and inadequate resuscitation of patients before surgery[7]. In contrast, mortality following elective repair, even in 'high-risk' patients, is now negligible[8] and postoperative stay is less than 5 days in the vast majority of cases[5,7], which is approximately half the mean postoperative stay of patients in this series. The cost effectiveness of a policy of prompt elective repair is immediately obvious and raises the question of why so many patients today still present with strangulation.

Only three patients (4 per cent) in this series strangulated while on the waiting list for elective repair, which would refute the suggestion by Allen *et al.* that many patients, particularly elderly patients, strangulate while languishing on operating waiting lists[3], and the study suggests that three other factors are primarily responsible. Firstly, a large proportion of hernias (40 per cent), particularly femoral, strangulated almost immediately, presumably before patient notification of the family doctor and certainly before elective repair could be carried out. Secondly, a significant percentage of patients (23 per cent) failed to notify their family doctor despite noting the hernia for at least 1 month, suggesting a lack of public awareness of the dangers of hernia strangulation. Thirdly, many patients (24 per cent) were known by medical personnel to have had a hernia but surgical assessment had not been arranged, suggesting a reluctance on behalf of non-surgical medical personnel to refer patients with known risk factors, factors which, if appropriately treated preoperatively, should no longer be considered contraindications to elective hernia repair, given the current status of local and regional anaesthesia[7].

This study supports the view that all patients with abdominal wall hernias should be offered surgery[3]. While accepting that an unavoidable number of patients will continue to present with strangulation immediately after their hernia develops, a policy of prompt patient notification of their family practitioner followed by prompt referral and elective repair will greatly reduce the current incidence of strangulated hernias in adults.

The review of adult intussusception in the Greater Glasgow Health Board area[1,2] is extended to incorporate a further 33 cases occurring between 1974 and 1988.

Adult intussusception is an uncommon condition, between two and three new cases occurring in a population of approximately 1000 000 per annum. Previous studies from both sides of the Atlantic[3–10] have noted that, in contrast to childhood, the majority of cases are secondary to a causal lesion In Glasgow, two previous studies[1,2] covering the period from 1954 to 1974 suggest that there is a local propensity toward an idiopathic aetiology in up to 50 per cent of patients. Cases of retrograde jejunogastric intussusception following gastroenterostomy, and rectal prolapse were excluded from the study.

Patients

All patients discharged from the five Glasgow teaching hospitals with a diagnosis of intussusception were identified through the Scottish Home and Health Department's computerized Diagnostic Coding Index (560·0). Thirty-three patients were identified in the period from 1974 to 1988; each was studied to identify the site, the causal pathology, the presenting features, the accuracy of preoperative diagnosis, the method of diagnosis and the success of treatment.

Results

Age at presentation ranged from 18 to 83 years. Abdominal pain, usually colicy in nature, was universal. The other presenting symptoms of vomiting, distension, diarrhoea, constipiation or rectal bleeding were more variable and were dependent on the site of the lesion in the gastrointestinal tract. An abdominal mass was identified at presentation in 12 patients (36 per cent), although its significance was usually missed. Diagnosis was made at laparotomy in 30 patients (91 per cent) with a mean delay from admission to diagnosis of 3 days. The site of intussusception was as follows: one pyloroduodenal, eleven enteric, five ileocolic, seven caecocolic and nine colocolic.

One patient, who presented with gastric outlet obstruction, had a negative endoscopy and barium meal and was diagnosed at laparotomy to have a retrograde intussusception of the duodenal mucosa. In the small bowel, the majority of intussusceptions proved to be idiopathic (59 per cent); the others resulted from benign or malignant submucosal lesions. In the large bowel a malignant cause was found in ten patients (63 per cent), a benign cause in four (25 per cent) and an idiopathic aetiology was unusual.

Thirty-two patients underwent laparotomy. One elderly woman died shortly after admission, the diagnosis being made at post mortem. In cases of secondary intussusception the procedure performed was dictated by the causal pathology (*Table 1*). In idiopathic lesions there was variation in management: three patients required resection of ischaemic bowel; of the two idiopathic large bowel cases, one had a resection, the other a caecopexy (neither have recurred); in the small bowel intussusceptions, two patients underwent resection, the remaining five simply required reduction without fixation. There was no perioperative mortality. In a follow-up ranging from 1 to 14 years, none of the patients has developed a recurrent intussusception.

Discussion

A further 33 cases of adult intussusception are presented. Combining the three Glasgow studies, there are 83 patients who have presented over 34 years, with idiopathic aetiology occurring in 36 cases (43 per cent). However, 56 (67 per cent) cases involved the small bowel, which is a considerably higher proportion than in other series[3–10], and it would appear that it is the frequency of small bowel disease that distinguishes this population, rather than a local difference in aetiology. Of the 36 patients with idiopathic intussusception, 19 required resection for irreducibility or infarction; the remaining 17 had simple reduction without fixation. No patient has developed a recurrent intussusception.

In conclusion, therefore, we would suggest that:

1. Small bowel intussusceptions are more common in the west of Scotland than in other reported series
2. Idiopathic intussusceptions may be adequately treated by reduction alone, provided the bowel is viable
3. Preoperative diagnosis is rare and demands a high index of suspicion.

Sister Mary Joseph's nodule: a study of the incidence of biopsied umbilical secondary tumours in a defined population

M. K. Heatley and P. G. Toner

Department of Pathology, The Queen's University of Belfast, Grosvenor Road, Belfast BT12 6BL, UK
Correspondence to: Dr M. K. Heatley

Metastasis to the umbilical skin, first described by Storer[1] and often known as Sister Mary Joseph's nodule, is generally taken as a rare sign of extensive intra-abdominal tumour spread, indicating a very poor prognosis[2,3]. We have reviewed 33 cases diagnosed by biopsy in Northern Ireland, over 15 years. For the first time for this condition, we have related the total number of biopsies to a known, stable population and to reported mortality figures for various primary malignant tumours in that population.

Methods

The histopathology records of the Royal Victoria Hospital, Belfast and the Belfast City Hospital between 1970 and 1984 incorporate 89 per cent of all surgical specimens for Northern Ireland. The notes and slides of each identified case were reviewed. Death certificates were examined in the cases of patients who died outside hospital. The annual incidence of biopsied umbilical secondary tumours was calculated in relation to the average total population of Northern Ireland during the study period. The relative frequency of umbilical secondaries was then calculated in terms of the mortality rate associated with each of the corresponding primary tumours, as reported in the official death certification statistics of the Registrar General for Northern Ireland

Results

All 33 cases studied (19 female, 58 per cent; 14 male, 42 per cent) were adenocarcinomas. The mean age on diagnosis was 64 years. Patients survived for between 1 week and 67 months, the mean survival time being 8 months. The primary tumour site was not identified in seven cases (21 per cent). It is of interest that the mean survival in this group was much greater than for any of the identified primary tumours. The commonest identified primary was ovarian carcinoma (eight cases, 24 per cent), followed by carcinoma of colon and stomach (six cases each, 18 per cent). Pancreas (three cases, 9 per cent), lung (two cases, 6 per cent) and kidney (one case, 3 per cent) were the other identified primary sites. The mean population of Northern Ireland over the 15-year period was 1550 100. The incidence rate of biopsied umbilical metastasis was thus 0·142 per 100 000 population per year.

In ten cases (30 per cent) the umbilical secondary was the first sign of malignancy, while in two other cases (6 per cent), the metastasis heralded a decline due to dissemination of a previously diagnosed primary. Cutaneous secondaries are usually associated with a rapidly fatal course but six of our patients (18 per cent) survived longer than 1 year and one lived for over 5 years.

Table 1 relates registered deaths to biopsied umbilical metastases. One such lesion relates to 129 recorded deaths for ovarian carcinoma, making this the primary tumour most likely to give rise to the phenomenon. The corresponding figures for gastric and large bowel primaries are 1:765 and 1:1044 reported deaths, respectively. In men, these were the two commonest sites, accounting for 64 per cent of cases in male patients.

Discussion

In this series an ovarian primary was the commonest identified cause of a biopsied umbilical secondary. In two other large series, stomach, colon, ovary and pancreas were identified, in that order, as the main primary sites[4,5]. The relative frequency will reflect the referral and work patterns of the hospitals on which any study is based. Previous authors have been unable to relate this condition to a defined population; the residential stability and administrative isolation of Northern Ireland has provided us with such an opportunity.

Sources of error include a 10 per cent under-estimation of total cases, owing to incomplete coverage. In the calculation of relative frequencies, there is additional uncertainty associated with death certification data. Autopsies were not carried out in any of these cases. The use of mortality as denominator over-estimates the relative frequency of umbilical secondaries from the less aggressive primary tumours, such as large bowel, reflecting their favourable cure rates. The absence of an effective cancer registry in Northern Ireland means that the corresponding incidence data, which would have been preferable for this calculation, were not available.

In 12 of our 33 cases (36 per cent), the biopsy diagnosis was

Table 1 *The numbers of umbilical metastases originating at each primary tumour site, the mean survival time for each primary site, the numbers of recorded deaths due to tumours at this site and the estimated relative frequency of biopsied umbilical metastasis*

Primary site	No. of cases 1970–84	Male	Female	Mean survival (months)	No of deaths 1970–84	Relative frequency of biopsied umbilical metastasis
Ovary	8	–	8	8	1036	1:129
Colon	6	5	1	4	6265	1:1044

of practical clinical significance. In the other 21 cases, the biopsy was either an incidental, cosmetic or palliative procedure. Wide variations in these categories can be expected in different populations, reflecting different surgical traditions and changing patterns of diagnosis and treatment. In many other cases, no doubt, the phenomenon was noted clinically but did not call for biopsy.

In conclusion, ovarian carcinoma was the commonest cause of Sister Mary Joseph's nodule, both in numbers and relative frequency. In men, carcinoma of stomach and colon predominated. This is a more common phenomenon than is generally appreciated and it is not invariably associated with a terminal illness.

Phenol treatment of pilonidal sinuses of the natal cleft

G. Stansby and R. Greatorex

Department of Surgery, The Ipswich Hospital, Ipswich, Suffolk, UK
Correspondence to: Mr G. Stansby, c/o Department of Surgery, The Royal Free Hospital,
Pond Street, London NW3 2QG, UK

Pilonidal disease of the natal cleft is a common condition responsible for much morbidity, and its treatment places a burden on hospital and community resources. Many methods of treating chronic pilonidal sinuses have been described and the optimum treatment remains a topic for debate. Phenol injection of pilonidal sinuses has been the routine practice of two consultant surgeons in Ipswich for over 15 years, while the remaining consultant surgeons excise and pack sinuses. The relative merits of these procedures, as used in 169 patients over a 15-year period, have been reviewed.

Patients and methods

The hospital records of patients presenting with acute or chronic pilonidal disease, between 1970 and 1985, were reviewed. Age, sex, presentation, number of sinus openings, treatment, complications, inpatient stay, and outcome were recorded.

During the period studied 226 patients were treated for natal cleft pilonidal disease. Seventy-four patients (49 male patients and 25 female patients) presented as emergencies with pilonidal abscess and 152 (114 male patients and 38 female patients) were referred with a chronic pilonidal sinus. Mean age at presentation was 26·6 years (range 14–62 years). Twenty-eight patients presenting with an abscess subsequently developed a chronic sinus, resulting in 180 patients seen for pilonidal sinus. Eleven received no treatment, 65 were treated by excision and packing and 104 received phenol injections.

Excision of sinuses was performed *en bloc* and the wounds were packed and allowed to heal by secondary intention. The technique of phenol injection was similar to that described by Maurice and Greenwood[1]. Under general anaesthesia, with an endotracheal tube, the patient was positioned prone and the buttocks liberally covered with paraffin jelly. Eighty per cent phenol was injected into the sinus, left for 1 min, and the sinus then curretted; this was repeated three times. Patients with asymptomatic, shallow sinuses were advised that treatment was unnecessary.

Following excision of sinuses, patients received daily dressings until discomfort subsided sufficiently to allow a district nurse to continue the dressings at home. Thereafter patients were reviewed at 2–3 week intervals until their wound healed. Patients treated by phenol injection were kept in hospital overnight, and allowed home the following day with instructions to bathe daily and keep the area shaved. Regular dressings and analgesia were not required by patients treated with phenol. Outpatients review was continued at 2–3-week intervals until the sinus healed. Fifty-two (80 per cent) patients treated by excision and 79 (76 per cent) of those treated with phenol were seen 3–6 months after healing to exclude or identify recurrence.

Results

An initial cure rate of 83 per cent was obtained following excision compared with 65·4 per cent following phenol injection. Second treatments using the same methods on individual patients improved these figures to 86 per cent for excision and 75 per cent for injection. Information on the number of sinus openings was available for 42 patients treated by excision and 65 patients treated by injection. Analysis of cure rate relative to number of sinus openings showed that for sinuses with one or two openings there was no significant difference between excision and injection.

Comparison of inpatient stay and time to healing revealed a significantly earlier discharge from hospital and shorter time to healing following phenol injection (*Table 1*) During a mean follow-up of 8 months (range from 3 months to 4 years) recurrent sinuses after initial healing occurred in ten patients treated by excision and 12 treated by injection.

Following 130 phenol injections in 104 patients sterile abscesses developed in seven and cellulitis in one patient. There was no relationship between number of sinus openings and development of an abscess. The abscesses and related sinuses were all cured by surgical drainage and the cellulitis settled with antibiotic treatment. No other complications were seen in either treatment group.

Discussion

Pilonidal sinus of the natal cleft can be a chronic, recurring condition which is difficult to cure. Many treatments have been proposed but few provided long-term good results. The traditional methods of *en bloc* excision and laying open of sinuses result in hospital admissions of 5–29 days, healing times of 6–10 weeks and recurrence rates of 8–21 per cent[2–5], similar to the findings in this series. Previous attempts to improve on these results by various methods of primary closure reduced the healing times to under 2 weeks, but hospitalization remained similar at 9–18 days and recurrence rates varied between an encouraging 2–4 per cent[6–8] and a disappointing 8–40 per cent[2–4,9,10]. The Millar–Lord technique[11] produces a healing time of 7 weeks and a recurrence rate of 23 per cent[12], similar to results following phenol injection.

There have been four small series reporting phenol injection of pilonidal sinuses and these describe hospitalization of 2–3 days, healing within 3–6 weeks, return to work in 1–2 weeks and recurrence rates of 9–27 per cent[1,13–15]. This report confirms the brief inpatient stay, the reduced time to healing and a recurrence rate similar to that following excision and packing. The 5·4 per cent incidence of sterile absence following

injection is disappointing, but might be reduced by more gentle injection of the phenol.

This study shows that for pilonidal sinuses of the natal cleft, with one or two openings, phenol injection is an effective treatment. The method produces results which are similar to those achieved by surgical excision but has the advantages of a reduced requirement for anagelsia and dressings, and a shorter inpatient stay and time to healing. We advocate phenol injection as the first line of treatment for uncomplicated pilonidal sinuses of the natal cleft but consider excision more suitable for complicated sinuses with three or more openings. The lack of long-term follow-up for both groups does not deter us from making this recommendation; late recurrence is recognized after all forms of treatment and the advantages of phenol injection, outlined above, encourage us to recommend treating any recurrence with a second application of phenol before resorting to more aggressive methods.

Serum phospholipase A_2 activity in acute pancreatitis: an early guide to severity

N. C. Bird,
A. J. Goodman and
A. G. Johnson

University Surgical Unit,
Royal Hallamshire Hospital,
Glossop Road, Sheffield S10 2JF,
UK
Correspondence to:
Mr N. C. Bird

Daily measurements of serum phospholipase A_2 activity were carried out on 73 consecutive patients admitted to hospital with acute pancreatitis. During the first 6 days there were significant differences in activity in those patients predicted as severe by multiple prognostic criteria when compared with those with mild disease. Follow-up studies at 6 weeks showed no difference between those graded as mild and those graded as severe at the time of attack. In the patients with elevated activity, nine had this at the time of admission and all were raised within 24 h. Elevated activity correlated well with the clinical outcome and showed good agreement with the multiple prognostic criteria in the prediction of severe disease. It is suggested that measurement of serum phospholipase A_2 activity may provide a simple test for the early identification of most patients with severe acute pancreatitis.

Keywords: Phospholipase A_2, acute pancreatitis

The use of multiple laboratory criteria[1,2] is a well established and widely used method for predicting severity in attacks of acute pancreatitis. In the early stages of the disease this system offers a significant improvement over clinical judgement for identifying severe attacks, but it can take up to 48 h to complete the assessment, by which time the advantage is lost[3]. A more rapid answer can be obtained by using the technique of diagnostic peritoneal lavage, but clinical reluctance and patient refusal have limited its application[4]. In recent years the measurement of serum phospholipase A_2 activity has been reported as providing a simple and rapid alternative for differentiating mild from severe disease. Studies from Finland[5,6] and Germany[7] have shown that in haemorrhagic pancreatitis the enzyme activity is significantly elevated early in the disease, whereas in oedematous pancreatitis only modest elevations occur. The question remains about how the measurement of phospholipase A_2 activity can help in discriminating mild from severe disease. This paper reports a prospective study measuring serum phospholipase A_2 activity during 73 attacks of acute pancreatitis. The results were compared with the multiple prognostic criteria for their accuracy in predicting severe acute pancreatitis.

Patients and methods

The study group comprised 73 consecutive patients admitted to the Royal Hallamshire Hospital with acute pancreatitis between December 1984 and February 1987. The diagnosis of acute pancreatitis was made on the finding of a serum amylase level >1000 units/l (Phadebas method, Pharmacia G.B. Ltd., Milton Keynes, UK) and a consistent clinical picture of abdominal pain. All patients were seen on admission by one of the authors (A. J. G.) and a full drug and alcohol history was taken. Blood samples were obtained for severity grading by the multiple prognostic criteria[2] and phospholipase A_2 analyses. Blood samples were taken for phospholipase A_2 analysis on admission and then daily for a period of up to 8 days. An additional sample was taken at the out-patient appointment 6 weeks after discharge from hospital.

All patients were initially treated under conservative management. This consisted of correction of fluid and electrolyte imbalance, nasogastric aspiration, and analgesia with opiates; antibiotics were not routinely given.

The biochemical and haematological tests for diagnosis and severity prediction were performed in the routine hospital laboratories. The phospholipase A_2 activity determinations were carried out using the method developed in our department[8]. Briefly, this involves quantifying the palmitic acid released as a result of the enzyme action on dipalmitoyl phosphatidylcholine, by capillary gas–liquid chromatography. The results are expressed in units per litre of serum.

Results

The aetiological association of the 73 attacks of acute pancreatitis are shown in *Table 1*. There was an equal number of men and women with a mean age of 59 years (range 23–85 years). The clinical outcome classified 22 patients as severe, with eight fatal attacks, four patients who developed pancreatic pseudocysts (>2 cm diameter), and ten patients who required a hospital admission, as a result of acute pancreatitis, of >14 days.

The phospholipase activities are shown in *Table 2*. Statistical analysis, using the Mann–Whitney *U* test, shows that there are significant differences during the first 6 days between attacks graded by prognostic indices, as mild and attacks graded as severe, but this disappears by the time of follow-up at 6 weeks (*Figure 1*).

In an attempt to define a level of phospholipase activity that would separate clinically mild from clinically severe disease, the data were reviewed retrospectively. The highest value from each clinically mild patient was taken and the mean and standard deviation were calculated. Two standard deviations above this mean value of 45 units/l gave a cut-off value of 85 units/l, above which the patients were graded as phospholipase A_2 severe. Of the 73 patients in the study, 11 showed values >85 units/l, of whom eight had been predicted as having severe disease by multiple prognostic criteria. There was no relationship between the aetiological factors and raised phospholipase activity, the aetiologies merely reflecting the group as a whole. The interesting finding was that nine of the phospholipase A_2 severe patients had raised activity on admission to hospital and all were elevated within 24 h.

Discussion

The success of the multiple prognostic criteria in predicting severe disease was similar in this study to those of previous reports[4,9]. Of the 16 patients with predicted severe attacks, eight died and, of the survivors, three were discharged from hospital within 14 days, giving a true positive prediction of 81 per cent. In the 57 patients predicted as mild, four of them developed pancreatic pseudocysts and four required a hospital stay >14 days, giving an accuracy of 86 per cent.

When phospholipase A_2 activity was used to assess severity the success for the severe cases was similar to that of the multiple prognostic criteria (χ^2 test with Yates' correction, $P<0·001$).

Ten of the 11 patients with raised activity had clinically severe disease (91 per cent true positive). However, the success for mild attacks was not so good and it is important to note that three deaths occurred in patients in whom no marked rise in activity was seen. One patient was an early death within 24 h from bilateral adrenal haemorrhage, and the other two were late deaths at 31 and 90 days respectively. Despite the fact that one of these late deaths was not pancreatitis related, all three had been predicted as severe attacks by multiple prognostic criteria. In the remaining 59 phospholipase A_2 mild cases there were four pancreatic pseudocysts recorded and four patients whose hospital stay was greater than 14 days, giving an accuracy of 82 per cent.

Although none of the tests used in the multiple prognostic criteria method for predicting severity of attack is specific for acute pancreatitis, the tests do, in combination, provide a reliable means of identifying patients with severe disease. This study has shown that the estimation of serum phospholiphase A_2 activity may provide a more rapid prediction of severity, elevated levels showing a good correlation with severe disease. The recent publication of methods[9,10] suitable for routine use should allow more widespread application of this technique.

APACHE II score in massive upper gastrointestinal haemorrhage from peptic ulcer: prognostic value and potential clinical applications

M. Schein and G. Gecelter

Department of Surgery, J G. Strijdom Hospital and the University of the Witwatersrand, Johannesburg, South Africa

Correspondence to:
Mr M. Schein, Department of Surgery, Medical School, York Road, 2193 Parktown, Johannesburg, South Africa

This study examined the prognostic value of the APACHE II scoring system in patients undergoing emergency operations for bleeding peptic ulcer. There were 96 operations for gastric ulcers and 58 for duodenal ulcers. The mean scores in survivors and in patients who died were 10·8 and 17·5 respectively. None of the 66 patients with an APACHE II score <11 died, while the mortality rate in those scored >10 was 22 per cent. In patients scored >10 non-resective procedures carried less risk of mortality than gastectomy. The APACHE II score is useful when measuring the severity of the acute disease and predicting the outcome in these patients. If used in daily practice it may assist the surgeon in stratifying patients into a low-risk group (score <11) in which major operations are well tolerated and outcome is favourable and a high-risk group (score >10) in which the risk of mortality is high and the performance of procedures of lesser magnitude is probably more likely to improve survival.

Keywords: APACHE II, outcome prediction, upper gastrointestinal haemorrhage, emergency gastroduodenal operations

The procedure of choice for the surgical control of a bleeding peptic ulcer is controversial. While some authors[1,2] advocate the use of truncal vagotomy and antrectomy (TV+A) for a bleeding duodenal ulcer, others[3] claim that truncal vagotomy and a drainage procedure (TV+D) is safer. The same argument involves the management of bleeding gastric ulcers. Whilst partial gastrectomy continues to be the procedure of choice in many major centres[1,2,4], others attribute lower mortality rates to more conservative operations such as TV+D[5] or simple undersewing of the ulcer alone[6].

The comparison of results is distorted by the fact that sicker patients are usually selected for the more conservative operations. Thus, for example, McGuire and Horsley[7], operating on bleeding duodenal ulcers, cited a mortality rate of 21 per cent for TV+A and 45 per cent for TV+D. It is widely recognized that elderly patients, especially those with associated medical disease, represent a 'high-risk' group that tolerates poorly the combined acute insult of bleeding and the subsequent operative procedure[3,8,9]. However, there is general lack of agreement about the definition of the 'high-risk' patient. Yajko *et al*[4] advocated TV+A for their 'good-risk' patients with bleeding duodenal ulcers; TV+D was reserved for the 'high-risk' group. The selection criteria for either group were not defined and were probably left to the clinical judgement of the individual surgeon. Likewise, Herrington and Davidson[1] would reserve TV+D for the 'extremely high risk patient who it is felt will not tolerate the more lengthy procedure' of TV+A for duodenal ulcers, and partial gastrectomy for gastric ulcers. Welch *et al.*[2] in a large retrospective study attempted to subdivide their patients into four risk-grade groups. Mortality rates were similar for TV+D or TV+A in all age and risk groups; precise definition of the various risk grades is not given. Rogers *et al.*[6] studied the surgical management of bleeding gastric ulcer patients in whom the mortality rate for partial gastrectomy was 26 per cent and for undersewing alone was 10 per cent. No evidence to support the similarity of their patients in terms of surgical risk is presented.

Five main factors determine the outcome of an acute disease: the patient's age, the prior health status of the patient, the severity of the disease, the type of the disease, and the treatment given. The APACHE II scoring system[10] has gained recent popularity in the measurement of severity of acute illness It takes into account the first three factors. Obviously, if the influence of any given therapy is to be assessed, the score should be determined before treatment is commenced. The predictive power of APACHE II has been validated in many acutely ill patients admitted to intensive care units with common medical and surgical diseases[10]. Others have found APACHE II to be useful in predicting outcome in intra-abdominal infections[11–13] and acute pancreatitis[14].

The reasons for this study are threefold: firstly, to attempt to validate the prognostic value of APACHE II in patients undergoing emergency operations for the control of bleeding peptic ulcers; secondly, to assess its usefulness as a potential clinical research tool; and, thirdly, to use this method for the stratification of patients according to their surgical risk to assist in making rational and objective treatment decisions

Patients and methods

All patients with upper gastrointestinal haemorrhage admitted to the J. G. Strijdom Hospital, Johannesburg are cared for by one surgical unit The 'on duty' surgical team assumes responsibility for resuscitation, endoscopy, surgery (if indicated) and future care of these patients

The decision to perform an emergency operation is taken by the consultant surgeon on duty, based on clinical and haematological evidence of persisting or recurrent bleeding The choice of procedure performed is left to the surgeon and no strict protocol has been laid down However, during the study period, the general trend was to perform partial gastrectomy for bleeding gastric ulcers and TV+D for duodenal ulcers.

All patients who underwent emergency surgery for bleeding peptic ulceration between 1980 and 1987 inclusive were identified from their discharge books and their summaries were retrieved Patients who

0007-1323/89/070733–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

underwent semi-urgent operations (i.e. elective procedures performed on the same hospital admission) were excluded.

APACHE II score was calculated according to the method of Knaus *et al.*[10]. For each physiological variable we included the most abnormal measurement of that variable within the 24 h before operation. In the situation in which a variable had not been measured in the 24 h before surgery, the last measurement of that variable before treatment was used If a particular variable was never measured, it was considered normal and a 0 score was entered. Similarly, applied retrospective APACHE II scoring was validated in patients with abdominal sepsis[11]. Any death during the first 30 postoperative days was considered an operative mortality.

Results

In the 8-year study period, 900 patients with upper gastrointestinal haemorrhage were admitted to our unit; a total of 154 patients underwent emergency surgery for bleeding gastric ($n = 96$) or duodenal ($n = 58$) ulcers. Clinical details of patients in both ulcer groups and their APACHE II scores are represented in *Table 1*.

Nineteen patients died (12·3 per cent). The mean age of the patients who died and those who survived was 71·7 and 58 years respectively. Twelve deaths were due to 'medical' causes such as respiratory, cardiac, renal or hepatic failure. Two patients had cardiac arrest in the perioperative period: one of them shortly after partial gastrectomy for bleeding gastric ulcer; the other, operated on for bleeding duodenal ulcer, shortly after induction of anaesthesia. Five deaths were due to 'surgical' causes: in three patients due to massive rebleeding following partial gastrectomy, and in two due to anastomotic leaks after partial gastrectomy and TV + D.

Table 1 *Patient details and mean APACHE II scores*

	Gastric ulcer	Duodenal ulcer
No. of patients	96	58
Male:female	59:37	41:17
Mean age (years)	59·6	61·2
Mean APACHE II score	12	10·9
Mortality rate (%)	12 (13)	7 (12)
Mean APACHE II score of survivors	11·4	9 8
Mean APACHE II score of patients who died	16·2	19·4

Overall, the mean APACHE II score in the 154 patients was 11·6 (range 2–25). The mean APACHE II score in patients who died was 17·5 compared with 10·8 in survivors.

An increasing APACHE II score was associated with an increased likelihood of mortality for patients with both gastric and duodenal ulcer (*Table 2*). Interestingly, none of the 66 patients with APACHE II score < 11 died, while the mortality in those > 10 was 22 per cent.

Table 3 demonstrates the mean APACHE II score and the mortality rates in patients undergoing different procedures. Patients in the gastric ulcer group, subjected to non-resective operations (undersewing or TV + D), had higher scores than those undergoing partial gastrectomy. This can obviously be attributed to selection of the lesser procedure for the clinically high-risk patient. That was not the case in the duodenal ulcer group where patients receiving TV + A and TV + D had almost similar scores.

Tables 4 and *5* examine the mortality rates for the different procedures performed in subgroups of patients with different APACHE II scores.

Table 6 shows the mortality rates of the various procedures in patients with scores > 10. Limited operations, such as undersewing or TV + D in the case of gastric ulcer and TV + D in duodenal ulcer, carried less risk of mortality than resective operations (partial gastrectomy or TV + A) in this high-risk group. These results, however, did not reach statistical significance.

Discussion

As pointed out above, the literature that deals with the management of massive upper gastrointestinal haemorrhage lacks precision and uniformity in its definition of the severity of illness of the patients studied and their operative risk. A better method is needed in the emergency preoperative evaluation of these patients. In this study we have attempted to find out whether the APACHE II system could achieve such a goal. Our results validate the prognostic value of the APACHE II scoring system in patients who undergo operations for upper gastrointestinal haemorrhage. It demonstrates that the increased surgical risk of the individual patient is reflected by the APACHE II score, which in turn correlates well with the probability of dying. Of course, a search for factors that influence mortality in patients with upper gastrointestinal bleeding has been attempted in the past[3,9]. The APACHE II

scoring system offers certain attractive advantages: its predictive power has been previously validated in a large number of critically ill patients admitted to intensive care units[10,15], in intra-abdominal infections[11–13], acute pancreatitis[14] and multiple trauma[16]. It measures the severity of the acute illness of the patient based on basic clinical examination (temperature, blood pressure, cardiac and respiratory rates and the level of consciousness) and a few simple laboratory investigations (red and white cell counts, serum sodium, potassium and creatinine levels, and arterial blood gas). In addition, it takes into account the patient's age and previous chronic health status, which in turn reflect their physiological reserve and their capability to withstand the combined insult of the acute disease and its surgical treatment. Consequently, a brief history and clinical examination combined with the above-mentioned laboratory variables should allow complete APACHE II scoring and precise stratification of patients to the various risk groups before operation in under half an hour.

All surgeons know that fit patients in good shape tolerate the operations well while the elderly and sick tend to fare badly. The mere fact that patients with low APACHE II scores survive and those with high scores die is therefore not a strong enough reason for surgeons to measure prognostic scores in their acute patients. What, then, are the practical applications of APACHE II scoring?

In this study, we divided our patient population into three prognostic subgroups. The first consists of patients with APACHE II score <11. Those in this group did well irrespective of the procedure selected; their youth and the relatively mild physiological compromise imposed by the haemorrhage on previously healthy organ systems allowed them to withstand any operative stress. The second group of patients with scores ranging between 11 and 20 represented a higher risk group with a higher mortality rate. The final group, with scores >20, consisted of severely compromised individuals who tolerated poorly any operation and hence had a high probability of dying. Similar patterns after division into three groups according to the APACHE II score were demonstrated in patients with abdominal infections[11,13].

Although the original APACHE II system was not developed as a basis for treatment in the individual patient, data from carefully described groups of patients can be used cautiously in decision making[17]. The knowledge that none of the patients in the present study with scores <11 died may suggest that operations of any extent would be relatively safe in such a subgroup. In this situation the objective scoring system should function as an aid to the well developed but subjective clinical judgement of the surgeon. The second and third groups represent severely compromised patients. Certainly, those with extremely high scores belonging to the third group would die despite maximal supportive therapy, and irrespective of the procedure chosen. It seems that in the majority of patients with APACHE II scores >10 the correct selection of the extent of the procedure may be important. Our study 'suffers' from paucity of high-scoring patients subjected to TV+A for bleeding duodenal ulcers or TV+D and/or undersewing alone for gastric ulcers. Our data imply, however, that in the high-risk patients, with scores >10, performing the lesser procedure may improve hospital survival.

Only one end-point, namely the death or survival of the patient, was used. Criteria such as the period of hospital stay or admission to an intensive care unit were not used; these may be influenced by the availability of facilities and differences in management policies between individual centres and clinicians.

Although there were no deaths among patients with scores <11 in this series, individuals with low scores do occasionally die. During the last 2 years we have prospectively measured the preoperative APACHE II scores in patients with intra-abdominal infections (M. Schein and G Gecelter, unpublished data). In over 100 patients studied to date we encountered two fatalities in those belonging to the low-risk group (<11), both dying after massive aspiration of gastric contents. Fatalities in the low-score group should be considered as 'unexpected', and are due to shortcomings in patient management.

The APACHE II score in its present form has a few noticeable weak points. For example, it does not take into account acute ischaemic electrocardiographic changes, the presence of severe arrhythmias or the history of a recent myocardial infarction – conditions which, if present, will add to the operative risk. A new version of the present score, the APACHE III, is in evolution in order to deal with these few deficiencies (W. A. Knaus, personal communication).

We conclude that the APACHE II score is useful in measuring the severity of acute disease and predicting the outcome in patients operated on for upper gastrointestinal haemorrhage. If used in daily practice as an objective aid to clinical judgement it may assist the surgeon in stratifying patients into a low-risk group in which major operations are well tolerated and outcome is favourable, and a high-risk group in which the probability of mortality is high and the performance of procedures of lesser magnitude is probably more likely to improve survival. Uniform scoring of the patients in these trials using a common language such as the APACHE II would improve patient stratification to the good-risk and poor-risk groups, enabling studies to be performed which would confirm or reject the suggestion that tailoring of the procedure to the patient's score would ultimately lead to improved survival.

Sigmoid volvulus in rural Ghana

E. J. Gibney

Holy Family Hospital, Berekum, Brong Ahafo, Ghana
Correspondence to: Mr E. J. Gibney, Department of Surgery, Beaumont Hospital, Dublin 9, Ireland

There is a marked geographical variation in the incidence of volvulus of the sigmoid colon. Holy Family Hospital, Berekum, Ghana lies in an area where sigmoid volvulus is especially common, and a detailed study covering the years 1975–82 was reported from Berekum by Schagen van Leeuwen[1].

This report records the experience with sigmoid volvulus over the following 5 years, from 1983 to 1987.

Patients and methods

The operative records of all patients treated for mechanical bowel obstruction at Holy Family Hospital, Berekum, between 1 January 1983 and 31 December 1987 were examined, as were the full medical records of all those patients treated for sigmoid volvulus. This 162-bed district hospital in the Brong Ahafo region of Ghana serves a population of 165 000 (1984 census)

Results

A total of 330 patients were treated for mechanical bowel obstruction during the period studied, of whom 73 (22 per cent) had volvulus of the sigmoid colon. The mean age of these 73 patients was 50·9 years, with the youngest aged 3 years and the oldest in his nineties. The male:female ratio was approximately 2:1 (48:25).

There were 12 deaths in the group, giving an overall mortality rate of 16 per cent. The main therapeutic procedure performed in each case and the associated mortality rate are shown in *Table 1*. The mortality rate was higher in female patients (24 per cent) than in male patients (12 per cent).

Table 1 *Main therapeutic procedure performed in 73 patients with sigmoid volvulus, and the associated mortality rate*

Procedure	No. of patients	No of deaths	Mortality rate (%)
Sigmoidoscopy and flatus tube insertion	15	2	13
Laparotomy and detorsion without subsequent resection	15	4	27
Elective sigmoid resection	35*	4	11
Emergency sigmoid resection	8	2†	25
Total	73	12	16

* Of the 35 patients in this group, 25 had had previous sigmoidoscopic insertion of a flatus tube and nine had had a previous laparotomy and untwisting of sigmoid volvulus. †One of these patients had survived an emergency Hartmann's procedure but died following an anastomotic leak after reanastomosis some months later

Discussion

Sigmoid volvulus is a dangerous condition with a significant risk of mortality. The principles of treatment are well established. Most patients can be successfully managed by Bruusgaard's method of sigmoidoscopy and the passage of a flatus tube[2] followed by elective sigmoid resection. A few patients need laparotomy to untwist the bowel, and occasionally emergency resection is required when non-viable bowel is present, when Hartmann's operation is the procedure of choice[1,3–5].

The number of cases of sigmoid volvulus presenting to Holy Family Hospital has fallen from an average of 18 per year (1975–82)[1] to 15 per year (1983–87). Coupled with the increase in population this probably represents a real decline in the incidence of the disease in the Berekum Jaman district.

The mortality rate has increased from 10 per cent in 1975–82 to 16 per cent in 1983–87. The reasons for this are not clear. The mean age of the patients was similar (48·7 and 50·9 years respectively), but there were relatively more female patients in the present study, in whom we noted a higher mortality rate. The results still compare favourably with those obtained in many western series[5,6].

There was a high mortality rate in those who rewquired emergency laparotomy. Of the 32 patients in this group, eight required emergency resection for non-viable bowel (25 per cent mortality rate). The other 24 patients had untwisting and deflation of the volvulus, with insertion of a flatus tube per rectum. Of these patients, nine subsequently underwent successful elective resection, but four of the other 15 died. Therefore the overall mortality rate in the 'laparotomy and untwisting' group was 17 per cent, which we consider to be high especially in view of the fact that 11 (46 per cent) of them went home without definitive treatment and therefore with a high risk of recurrence[7]. Shepherd[8] had similar results, with eight deaths in 49 patients (16 per cent mortality rate) treated by laparotomy and untwisting.

We confirm from this study that, for all its apparent simplicity, laparotomy and detorsion of sigmoid volvulus with viable bowel carries a significant mortality, and that it may not be the procedure of choice in those patients in whom sigmoidoscopic intubation has failed to deflate the bowel. Anderson and Lee[5] came to the same conclusion but the best procedure in this situation remains controversial (Hartmann's procedure, or resection and anastomosis with or without a 'protective' transverse colostomy).

Acknowledgements

I wish to thank the medical staff of Berekum, Mr Nicholas Frimpong of the Medical Records Department, and the Agency for Personal Service Overseas, without whom this study would not have been possible.

Conservative proctocolectomy: a dubious option in ulcerative colitis

R. W. Talbot,
J. K. Ritchie and
J. M. A. Northover

Department of Surgery, St. Mark's Hospital, London, UK
Correspondence to:
Mr R. W. Talbot, Poole General Hospital, Long Fleet Road, Poole BH15 2JB, UK

Conservative proctocolectomy was performed for ulcerative colitis in 19 patients, Crohn's disease in three and familial adenomatous polyposis in one. Healing was uncomplicated in only three patients (13 per cent). Eleven developed an anal discharge and nine an infected pelvic haematoma despite peranal drainage. Fourteen patients developed pelvic sepsis and, despite surgical curettage in 11, none healed. Six of these patients have had the anal sphincter divided, with healing in only one, and the anal canal has been excised in two. Eleven patients have ultimately healed at a median time of 28 months and eight have persistent sepsis after a median period of 45 months. Two patients with sepsis have had a successful ileoanal anastomosis. Conservative proctocolectomy cannot be recommended as a definitive operation for ulcerative colitis even though it may permit a subsequent restorative procedure.

Keywords: Ulcerative colitis, proctocolectomy

The 'conventional' operation for ulcerative colitis is a total proctocolectomy with an incontinent ileostomy[1]. Over the last 10 years, restorative proctocolectomy with removal of the colon, rectum and upper anal canal mucosa, and anastomosis of an ileal pouch to the anus, has become increasingly popular[2].

A modified technique[3] for total proctocolectomy, removing the colon and rectum whilst conserving the anus, was described in 1953. The aim of this operation was to avoid the perineal dissection which was often associated with considerable hypotension Colorectectomy and conservation of the anus was recommended more recently for inflammatory bowel disease[4] because it avoided a perineal wound and in women preserved the perineum for vaginal support.

This operation, alternatively called a 'conservative proctocolectomy', removes the entire colon and rectum and the mucosa from the upper anal canal but preserves the mucosa of the lower anal canal and the internal and external sphincters. Conservative proctocolectomy may be indicated in patients with ulcerative colitis when Crohn's disease cannot be excluded or when there is a coexistent adenocarcinoma. It may also be an option in patients who decline a restorative procedure but wish to preserve their options for the future. This retrospective study reports our experience of conservative proctocolectomy and poses the question: can this operation be recommended in ulcerative colitis?

Patients and methods

Twenty-three patients had a conservative proctocolectomy at this hospital between 1975 and 1987. The colon and rectum were dissected to the level of the pelvic floor and the rectum was transected under upward traction. Using this technique the mucosal transection is close to the dentate line and any residual mucosa can be removed by peranal mucosectomy. The pelvis was drained by a tube drain through the anal canal in 19 patients and by suction drainage from above in four. The case notes have been studied retrospectively to determine the indication for anal conservation, postoperative pelvic and anal complications, and the frequency and outcome of subsequent restoration.

Results

Conservative proctocolectomy was performed for ulcerative colitis in 19 patients, Crohn's disease in three patients and familial adenomatous polyposis in one. There were 13 men and ten women with a median age of 34 years. Most of the patients had this operation because they declined a restorative procedure but wanted to retain their option for a later pouch (*Table 1*).

Uncomplicated healing occurred in only three patients (13 per cent), in one who had Crohn's colitis and in another following removal of an incontinent ileoanal pouch. During the postoperative period, 11 patients developed an anal discharge and nine patients an infected haematoma, which drained on digital examination or through a proctoscope. Infected haematomas were unrelated to the type of pelvic drainage employed.

Six of the 11 patients with an anal discharge had no further treatment and the discharge ceased in four after 24, 30, 36 and 36 months, and persisted in two after 9 and 38 months. The remaining five patients, together with all nine with an infected haematoma, developed chronic pelvic sepsis. The characteristic finding in these patients on digital examination was a normal anal canal closed at its upper end except for a small sinus into a pelvic cavity. The cavity could be confirmed radiologically (*Figure 1*).

Management of the sepsis that occurred in 14 patients is detailed in *Figure 2*. One patient healed with no further treatment but a total of 22 operations were performed on the other 13 patients. Two patients had an ileoanal pouch anastomosis. In both patients the operation was recorded as being technically difficult One patient was lost to follow-up abroad and the other had a good result, emptying the pouch spontaneously five times daily but with some nocturnal soiling. Curettage was performed, under general anaesthetic, in the remaining 11 patients but failed to eradicate the sepsis. Six patients went on to division of the anal sphincter in an attempt to provide drainage of the pelvic cavity. Sepsis was eradicated in one patient by sphincter division, two patients healed after excision of the anal canal for sepsis persisting despite sphincter division, and three have continuing sepsis The current outcome of these patients is summarized in *Table 2*.

Discussion

After intersphincteric dissection of the anal canal with primary suture of the perineal wound, primary healing occurs in about

50 per cent of patients and in 82 per cent the wound will be healed within 12 months of surgery[5]. The uncomplicated healing in only 13 per cent in this series after conservation of the anal canal compares unfavourably with this. None of these patients had perineal sepsis preoperatively. Postoperative sepsis was unrelated to the type of drain used. Ultimately, healing occurred in 11 patients (48 per cent) at intervals from 12 to 36 months (median 28 months) after the proctocolectomy, but only after sphincter division in one and sphincter division and anal excision in two.

Only two patients have subsequently had a restorative ileoanal anastomosis. Obviously, the optimal time to perform a restorative procedure is before the sphincter is damaged either by sepsis or by attempts to eradicate that sepsis. The procedure was difficult to perform in these two patients because of scarring in the pelvis, but there were no problems in completion of the anastomosis. Neither patient had any septic complications postoperatively and both have had their ileostomy closed. One of the concerns about pelvic sepsis in restorative proctocolectomy is the adverse effect of the resulting fibrosis and scarring on evacuation and control of the pouch. Two recent studies have suggested that once sepsis has been eradicated the function of the pouch is not usually compromised[6,7] unless an anastomotic stricture develops, in which case there is a higher chance of being unable to evacuate the pouch spontaneously[8].

Pelvic sepsis caused significant morbidity in 11 patients. Unlike the sepsis that sometimes follows intersphincteric excision of the anus, drainage of pus from the pelvic cavity is inadequate through the anal canal. This probably accounts for persistence of sepsis after drainage of a postoperative haematoma and for the failure of curettage to expedite healing. Sphincter division alone was unsuccessful in eradicating the sepsis in five of six patients, and two went on to intersphincteric excision of the anal canal. Once the sphincter has been divided, restoration will be impossible and it might be advisable to proceed immediately to anal excision when chronic sepsis has become established, unless restoration is indicated at that time.

Conservation of the anus is not without its complications. With only two patients proceeding to restorative ileoanal anastomosis, we cannot draw any firm conclusions about whether this is a viable option but if 'early' restoration is contemplated it would seem advisable to perform it at the initial operation. There is recent evidence that coexisting adenocarcinoma is not a contraindication to ileal pouch–anal anastomosis at the time of the initial resection[9]. If restoration is anticipated as a 'late' option, dissection below the peritoneal reflection should be avoided retaining a short rectal stump. If retention of a short rectal stump is contraindicated, a conventional intersphincteric dissection of the anal canal is advisable although the anal canal could be conserved if the patient is fully aware of the likelihood of chronic anal discharge or pelvic sepsis. These complications are incompatible with the desire of many patients to undergo the procedure that 'offers the best guarantee of trouble-free return to normal life and employment'.

UK

Univariate and multivariate analyses have been used to assess the influence of 14 variables on the results of 65 consecutive ileoanal pouch procedures over 5 years. There were nine failures requiring intubation, ileostomy or pouch excision. There was a significant association between failure and pelvic sepsis ($P<0{\cdot}05$, $n=8$), endoanal mucosectomy ($P<0{\cdot}05$, $n=7$), preservation of a long rectal cuff ($P<0{\cdot}05$, $n=5$) and lack of experience with the operation ($P<0{\cdot}05$, $n=8$). Of 49 patients with preoperative evidence of ulcerative colitis, three are now known to have Crohn's disease. Functional outcome was significantly impaired in patients who developed pelvic sepsis ($P<0{\cdot}01$) or a postoperative fistula ($P<0{\cdot}05$), and who had an endoanal mucosectomy ($P<0{\cdot}05$). Success with ileoanal pouch reconstruction increases with experience. Avoidance of sepsis is associated with a lower failure rate, improved functional results and reduced hospital stay. Preliminary colectomy is also advised to exclude Crohn's disease if the diagnosis is in question.

Keywords: Restorative proctocolectomy, morbidity, complications, functional results, factors, pelvic sepsis

Restorative proctocolectomy with ileonal–pouch anastomosis has been used in the UK since 1976 for the treatment of ulcerative colitis and familial adenomatous polyposis[1]. We have also found that the operation may be used for patients with severe megacolon and megarectum associated with stasis and obstruction. During this time there have been various modifications in surgical technique. These include the design of the pouch[2–5], the extent of rectal resection[6–8], the need to divide mesenteric vessels to achieve adequate length of the pouch[9], and techniques that minimize damage to the anal sphincters and pelvic floor[10]. In addition to all these factors is the acquisition of personal skills with the procedure[3,4]. We have used univariate and multivariate analyses to examine the influence of various factors on success, postoperative complications and functional results in our first 65 patients. The factors studied are listed in *Table 1*.

Methods

Analyses

The data are derived from all patients having a restorative proctocolectomy in this hospital who have been followed up for more than 6 months after restoring intestinal continuity.

All patients with a functional pouch were interviewed personally and examined in June and July 1988. Frequency of defaecation during the day and at night in the month before interview was recorded on a diary card. A functional score (0–12) recorded the presence or absence of 12 variables. The functional score was based on discussions with other colleagues engaged in evaluating results of restorative proctocolectomy. The functional score was derived by assigning a single point to the following functions: daily frequency >5, daily frequency >7, nocturnal frequency >1, urgency, soiling during the day, soiling at night, incontinence, failure of discrimination, use of antidiarrhoeals, dietary restriction, and use of pads during the day and at night. A postoperative complication score (0–8) recorded postoperative bleeding, wound and pelvic sepsis, anal stenosis, anal or pouch cutaneous fistula, intestinal obstruction and 'pouchitis'. Failure was defined by one of three criteria: the need for intubation (stricture, $n=1$), the need to raise an ileostomy after previous closure (severe diarrhoea, $n=1$) or excision of the pouch (sepsis, infarction, fistula, diarrhoea or unacceptable functional results, $n=7$).

Univariate analysis used the Mann–Whitney *U* test or Fisher's exact test. Multivariate analysis using principal components and Fisher's linear discriminant analysis was performed to identify the variables that predisposed to complications, poor functional results or failure.

Surgical variables

Restorative proctocolectomy was either a one-stage procedure ($n=36$) or performed after a previous emergency colectomy ($n=29$): 12 had mucous fistula, 13 had a long rectal stump oversewn, but in four cases the rectal stump was closed at the level of the levator ani.

In the earlier part of this series the rectum was mobilized using a long perimuscular procedure, the superior haemorrhoidal artery was preserved, and the rectum was often divided 2–3 cm above the pelvic floor ($n = 14$) However, as the pelvic autonomic nerves can be identified and preserved even after pedicle ligation of the superior haemorrhoidal vessels, the entire rectum is now excised with the mesorectum to the pelvic floor with the superior haemorrhoidal vessels ($n = 51$).

In the early part of this series the anorectal mucosectomy was performed entirely as an intra-anal procedure using a Parks' anal speculum ($n = 17$) During the past 2 years, since adopting the practice of complete rectal excision, anal mucosectomy has been performed in continuity with the rectum to avoid potential damage to the anal sphincters ($n = 48$).

With the exception of two early patients having a triple lumen S pouch, pouch construction has either been with the double lumen J pouch ($n = 46$) or the quadruple W pouch ($n = 17$)

Initially little attention was taken over dividing vessels in the small bowel mesentery ($n = 23$), and consequently some anastomoses were performed under tension and eight were complicated by stricture. A more extensive vascular mobilization is now used ($n = 42$) The origin of the superior mesenteric vessels is freed from the duodenum and the pancreas The terminal ileal arcades are carefully preserved, but proximal vessels preventing adequate distal mobilization are divided provided the peripheral arcades are intact. Occasionally the superior mesenteric pedicle has been divided if adequate length could not be achieved by other means Using this technique, only four strictures have been recorded but one pouch became ischaemic

In this series the ileoanal anastomosis was invariably sutured, using interrupted 3–0 Vicryl® (Ethicon Ltd, Edinburgh, UK) on a strong half-circle needle either at ($n = 56$) or 2 cm proximal to ($n = 9$) the dentate line None of the ileoanal anastomoses were stapled in this series.

Results

Eight patients had familial adenomatous polyposis. Eight patients with megarectum could not defaecate after a previous subtotal colectomy and ileorectal anastomosis The remaining 49 patients had inflammatory bowel disease of whom four are now known to have Crohn's disease

Failures

Nine patients have been classified as failures The details of these patients are listed in *Table 2*.

The failure rate in the first half of the study (25 per cent) was significantly higher than in the second half of this series (3 per cent; Fisher's exact test, $P < 0.02$). Eight of the failures had pelvic sepsis. Two failures were associated with Crohn's disease Seven of the nine failures had an endoanal mucosectomy, five being associated with the retention of a long rectal cuff; in two abdominal mucosectomy was impossible because the rectal stump had been divided at the level of the levator ani

Multivariate analysis indicated that failures were significantly greater after endoanal mucosectomy ($P < 0.05$), retention of the rectal cuff ($P < 0.05$), pelvic sepsis ($P < 0.05$) and surgical inexperience ($P < 0.05$)

Complications

Complications occurred in 25 patients (45 per cent) and are listed in *Table 3* In the first half of the series 19 patients developed complications (59 per cent) compared with ten in the second half (30 per cent); the difference is not significant

Bleeding. Two patients bled from within the sleeve of a long rectal cuff; both eventually had their pouch excised. One episode of bleeding was due to over-anticoagulation, the other was a secondary haemorrhage from sepsis

Sepsis. Despite the use of perioperative antibiotic cover, 21 patients developed postoperative sepsis (32 per cent). Eleven patients developed wound infections. Sixteen operations were complicated by pelvic sepsis (25 per cent). Eight of the 16 patients with pelvic sepsis were in the group classified as failures.

41	8	31	UC	W	+	+	+	–	–	+	–	–	*

No. in series	Problem	Result
1	Failure to evacuate, incontinent, long efferent limb, stenosis	Pouch excision (24 months)
2	Anovaginal fistula repair, stenosis	Intubation (6 months)
7	Enterocutaneous fistula, incontinent, persistent sepsis	Pouch excision (10 months)
8	Intestinal obstruction, infarction + resection, diarrhoea	Loop ileostomy (10 months)
10	Bleeding in rectal cuff – anticoagulated, sepsis	Pouch excision – emergency (21 days)
21	Severe diarrhoea	Pouch excision (12 months)
23	Enterocutaneous fistula, stenosis, incontinent	Pouch excision (10 months)
25	Enterocutaneous fistula, stenosis, incontinent	Pouch excision (12 months)
41	Ischaemic pouch and distal small bowel, tight trephine for loop ileostomy	Pouch excision (13 days)

* Unevaluable because intestinal continuity was not restored. UC, ulcerative colitis; RE, regional enteritis (Crohn's disease), PC, previous colectomy, VM, vascular mobilization, CI, covering ileostomy, EM, endoanal mucosectomy; LRC, long rectal cuff, PS, pelvic sepsis; AS, anal stenosis, F, fistula

Stenosis. Twelve patients developed stenosis at the ileoanal anastomosis (18 per cent); in one case this was present preoperatively from previous sepsis. Two strictures occurred after successful repair of anovaginal fistula. Eight of the strictures were associated with pelvic sepsis when there had been no attention to mesenteric vascular mobilization Four patients with strictures were classified as failures; the remaining eight patients have been successfully managed by gentle dilatation.

Fistula. There were nine fistulae, three from the pouch–anal anastomosis to the vagina and six enterocutaneous fistulae. However, three of the six enterocutaneous fistulae occurred after pouch construction from small bowel damaged at laparotomy ($n=1$) or ileostomy closure ($n=2$); all of these fistulae closed spontaneously. Of the remaining enterocutaneous fistulae two occurred from the ileoanal anastomosis (both requiring pouch excision) and one from the closed end of the ileum in a patient later discovered to have Crohn's disease requiring pouch excision.

Obstruction. Nine patients developed intestinal obstruction One patient with obstruction was designated a failure due to a small bowel infarction 10 months after operation, which required extensive resection. Five of the nine patients with intestinal obstruction required a laparotomy, one of whom developed an enterocutaneous fistula from operative damage (see above).

'Pouchitis'. Only six patients in this series developed 'pouchitis' (9 per cent). All presented with severe diarrhoea, four had joint pains and fever with systemic illness. All patients had some degree of anal stenosis at the onset of symptoms. All patients responded to oral metronidazole but one relapsed after discontinuing therapy.

Clostridium difficile diarrhoea. Two patients with severe diarrhoea were found to have *C. difficile* on stool culture. Neither case was associated with cytotoxin and both improved with vancomycin therapy.

Multivariate analysis indicated that the only factor to be associated with a significant increased complication rate was endoanal mucosectomy ($P<0{\cdot}05$).

Hospital stay

Total hospital stay ranged from 12 to 62 days (median 21 days). Using a multivariate analysis, the following factors were significantly related to prolonged hospital stay: preservation of the rectal cuff, extent of vascular mobilization, method of mucosectomy, experience of the surgeon, pelvic sepsis, anal stenosis and postoperative fistula ($P<0{\cdot}05$).

Function

Functional results were available in only 63 patients because two patients had had early pouch excision. The functional results have been included in the seven additional patients who are now classified as failures (*Table 4*).

Table 4 *Functional results*

	No. of cases	No. of failures
Frequency >7/day	14	2
Frequency >1/night	26	6
Urgency	3	1
Soiling by day	3	2
Soiling at night	9	3
Incontinence	6	4
Failure of discrimination	7	2
Use of antidiarrhoeal agents	31	7
Dietary restriction	10	5
Use of pads by day	4	4
Use of pads at night	11	5
Total	63	7

Two patients (both failures) had early pouch excision and could not be evaluated

One of the principal components of the functional score was frequency of defaecation, which varied considerably with duration of follow-up. A median frequency of seven bowel actions per day and twice at night was recorded in the first 6 months after ileostomy closure. By contrast, the median frequency 12 months after ileostomy closure was only five times per 24 h and after 24 months was only four times in 24 h. Median frequency of defaecation was five times in 24 h after J pouch construction compared with four times in 24 h in patients with a W pouch. Pelvic sepsis influenced stool frequency, the median frequency being eight bowel actions in 24 h in 16 patients who developed pelvic sepsis compared with four stools per 24 h in the remainder (Fisher's exact test, $P<0{\cdot}05$).

Analysis of the 56 patients who were not classified as failures indicated that soiling occurred in only one patient during the day but six patients leaked at night. Only two patients have episodes of frank incontinence. Six patients need to wear pads at night but none during the day. Twenty-four patients continue to take antidiarrhoeal agents (43 per cent) but only five need to restrict their diet (9 per cent).

When functional scores were analysed in all patients by multivariate analysis, only pelvic sepsis and endoanal mucosectomy ($P<0{\cdot}05$) significantly influenced the functional outcome. Both soiling and the use of pads were significantly more common in patients having endoanal mucosectomy ($P<0{\cdot}05$) and in those developing pelvic sepsis ($P<0{\cdot}01$). There was no evidence that age or previous colectomy had any adverse influence on functional outcome.

Discussion

In international terms this is a small series of ileoanal–pouch anastomoses[11–17]. Unlike the two other UK centres with a comparable experience of restorative proctocolectomy[18,19], the series in question spans only 5 years. The St. Mark's Hospital experience includes three different pouch designs, and operations by at least three different surgeons spanning the last 10 years[20]. The Leeds experience is only a little shorter and includes straight ileoanal anastomoses, at least three different pouch designs and variable preservation of the anal transition zone[21]. The purpose of this review has been to analyse the influence of changes in surgical technique and experience in a consecutive group of 65 patients operated on by one person.

This multivariate analysis has confirmed the overwhelming importance of pelvic sepsis and total rectal excision on complications, functional results and hospital stay. By contrast, pouch design, previous colectomy, age and the sex of the individual had no apparent influence on the results. There was a significant association between failure and pelvic sepsis, endoanal mucosectomy, retention of a long rectal cuff and experience with the operation.

Crohn's disease was associated with failure in two out of four cases. The diagnosis of Crohn's disease was associated with fistula and sepsis in one patient and incapacitating diarrhoea in another, but there are two patients with known Crohn's disease who have had an excellent functional result for over 3 years. Despite preoperative endoscopic biopsies the ultimate diagnosis of Crohn's disease was made from colectomy specimens in three patients and only from the excised pouch in the other. As previous colectomy has been shown to have no adverse effect on complications and the functional score, we believe that preliminary colectomy should be advised if the diagnosis of ulcerative colitis is in doubt. Under these circumstances, construction of a mucous fistula or oversewing the rectum well above the sacral promontory makes subsequent rectal excision much easier. The resection specimen should be scrutinized by an experienced histopathologist. No failures occurred in patients with polyposis or megarectum.

Age does not seem to be a specific contraindication to restorative proctocolectomy and three patients over 55 years of age have had excellent functional results. Motivation, personality and perhaps intelligence are important considerations in selection of patients.

Restorative proctocolectomy is not suitable for all patients with ulcerative colitis[20,22]. During this experience, 17 patients have undergone conventional proctocolectomy because they were considered unsuitable for this procedure. The reasons for conventional surgery were age greater than 60 years in three, severe psychiatric disease in four, preference for conventional ileostomy even after counselling in four, perianal disease in one, low IQ in two, and an over-riding desire to return to work with minimal delay in three. In our view the group of patients with ulcerative colitis who are most suitable for a restorative procedure are those with a short history of disease requiring emergency colectomy. All of these patients should be offered counselling from a patient who has had a successful pouch as well as from patients with a well functioning ileostomy.

The quadruple pouch has a larger capacity and is more compliant than the triple or double lumen pouches[23,24], consequently frequency of defaecation is less[25,26]. However, in our experience, postoperative complications and functional results were similar when the J and W pouch were compared. In this study pelvic sepsis had a profound influence on pouch function[27] and is probably more important than pouch design.

The 19 patients who did not have a covering loop ileostomy are of some interest. Although there were no complications, severe postoperative diarrhoea led to a prolonged hospital stay in four patients. Nevertheless, hospital stay was reduced to a median of 16 days by avoiding a proximal stoma. Although a successful outcome is possible without a loop ileostomy[28], some patients suffered transient severe diarrhoea, which may be psychologically damaging early after operation. On the other hand, the dangers of closing a loop ileostomy are avoided[29,30].

Considerable care and judgement must be exercised in deciding when to reoperate for intestinal obstruction; unnecessary laparotomy carries the risk of damaging the small bowel whilst delayed management resulting in infarction may compromise any hope of an acceptable functional result. Iatrogenic enterocutaneous fistulae from surgical damage or ileostomy closure all resolved with conservative therapy. All three pouch–cutaneous fistulae required pouch excision, one because of Crohn's disease, the others because of anal stenosis. Two of the three anovaginal fistulae were associated with a high anal anastomosis and sepsis resulting in suprasphincteric fistulae. The other was a late fistula from an anal gland infection. All were successfully repaired, but two patients developed anal stenosis.

In our view, pelvic sepsis has been the factor of greatest prognostic importance in determining poor function and potential failure. Pelvic sepsis was more common in the earlier part of this series when extensive vascular mobilization was not used and a long rectal cuff was retained[31]. We believe that it may be necessary to divide up to three major vessels in order that the apex of the pouch can reach the dentate line without being under any tension[32]. However, there is a small risk of infarction. Abdominal mucosectomy itself may not be critical in achieving improved functional results but endoanal mucosectomy can be associated with soiling if there has been prolonged anal retraction.

These data emphasize the learning curve of surgeons undertaking restorative proctocolectomy for the first time. We would argue, therefore, that the operation should be confined to a few centres capable of gaining wide experience of the operation so that interested surgeons can be taught to perform the operation safely. Audit of our results suggests that avoidance of pelvic sepsis by complete rectal excision and abdominal mucosectomy has been associated with improved functional results. If the underlying diagnosis is in question, we would now advise a preliminary colectomy, as function is not impaired by constructing a pouch as a secondary procedure.

It is widely believed that rectal polyps presage colonic polyps in the familial polyposis syndrome (FPS). Accordingly, rigid proctosigmoidoscopy has been justified as the sole means of presymptomatic detection of polyps in FPS[1]. We report a case of FPS with multiple colonic polyps, adenocarcinoma in the transverse colon, and a rectum macroscopically free of polyps.

Case report

An asymptomatic 39-year-old woman with a family history of FPS was referred for a routine examination. There was an osteoma 6 × 8 mm in the right temporal bone The rigid proctosigmoidoscope could not be inserted beyond 17 cm. The rectal mucosa was macroscopically normal. Two small polyps were seen in the distal sigmoid at 17 cm. Colonoscopy revealed scattered polyps in the sigmoid colon, with increasing numbers proximally, and more than 200 in the ascending colon. A prophylactic subtotal colectomy with ileorectal anastomosis was performed. In the resected specimen, myriad 0·1–0·5-cm polyps covered the mucosa of the proximal colon. There were fewer polyps more distally, and only ten in the distal 4 cm of the specimen. Microscopy showed adenomatous polyps and multiple foci of adenomatous change. There was also a 1·5 × 1·7-cm ulcerated, sessile, moderately well differentiated adenocarcinoma in the mid-transverse colon, infiltrating submucosa to the muscularis propria No lymph node metastases were found.

Discussion

Data on the distribution of polyps in FPS come from Bussey[2]. In 18 colectomy specimens, polyps showed a predilection for the left colon. The rectum was not examined. However, in 39 per cent of the cases, there was a greater number and density of polyps proximal to the splenic flexure.

Three large series have reported the apparent universal occurrence of rectal polyps in FPS patients with multiple colonic polyps. In two, the diagnosis was based solely on proctosigmoidoscopic findings[2,3]. Cases with colonic polyps in the absence of rectal polyps would not have been diagnosed until rectal polyps appeared. In the third, negative proctosigmoidoscopy was followed by a double contrast barium enema[4]. This examination is negative in about 75 per cent of cases where polyps are found at colonoscopy[5,6].

Several reports of FPS have alluded to rectal sparing in the presence of multiple colonic polyps[7,8]. Most notably, Harvey *et al.*[9] described 34 patients from FPS families. Four had no rectal polyps, and two of those had colon cancer at the time of diagnosis. In the Mayo Clinic series of 178 patients with multiple polyposis, 35 had no rectal polyps[10,11]. While some of these patients may not have had FPS, one of the 35 had a family history of FPS and nine had more than 100 colonic polyps.

The conclusion that cancer may develop before polyps appear in the rectum has profound implications for the selection of procedures for screening FPS families. The limited area of colorectal mucosa accessible through the rigid proctosigmoidoscope and the variability in the distribution of polyps in FPS suggest that flexible sigmoidoscopy or colonoscopy should be the screening procedure of choice for early detection of colorectal polyps in members of FPS kindred.

Operative mortality following surgery for colorectal cancer

J.-L. Canivet, P. Damas, C. Desaive* and M. Lamy

*Departments of Anaesthesiology and *Surgery, University of Liège, Belgium*

Correspondence to:
Dr J.-L. Canivet, Department of Anaesthesiology, Centre Hospitalier Universitaire de Liège, Domaine Universitaire du Sart Tilman—B 35, 4000 Liège 1, Belgium

From 1973 to 1986 at the Baviere Hospital, University of Liège, 476 patients underwent surgery for colorectal cancers. The overall operative mortality rate was 13·4 per cent. The following postoperative life-threatening complications occurred: myocardial infarction (14 per cent of the postoperative deaths) during the first three postoperative days; bronchopneumonia (27 per cent of the postoperative deaths) mainly during the first postoperative week; pulmonary embolism (17 per cent of the postoperative deaths) mainly during the second postoperative week, anastomotic leakage and cerebrovascular accident (14 and 8 per cent of the postoperative deaths respectively) mainly during the third and fourth postoperative weeks. Specific risk factors were chronic obstructive airways disease associated with a higher incidence of postoperative bronchopneumonia, and previous myocardial infarction associated with postoperative myocardial infarction and pulmonary embolism. General risk factors were old age and emergency procedure, both of which were associated with a higher incidence of infectious complications. The operative mortality rate fell from 20·1 per cent in the 1973–79 period to 7·8 per cent in the 1980–86 period.

Keywords: Colorectal cancer surgery, postoperative complications, operative mortality

Surgical resection is the only curative treatment in colorectal cancer; resection of the tumour may improve the quality of life in advanced incurable disease. Thus an increased operability and resectability rate should be the first step towards an improvement in the survival rate and the quality of life of these patients[1–6,13]. Others have reported that despite the increased number of aged and debilitated patients undergoing surgical treatment there has been an improvement in operative mortality recently[2,3]. We therefore decided to investigate whether this reduction in perioperative mortality rate had occurred in our institution. A retrospective analysis of patients operated on between 1973 and 1986 was made. Risk factors were reassessed and the type and timing of postoperative life-threatening complications were related to postoperative mortality. Two 6-year periods were compared: 1973–79 and 1980–86.

Patients and methods

From 1973 to 1986 at the Baviere Hospital, University of Liège, 476 patients (210 women, 266 men) underwent surgery for colorectal cancer. The mean age was 68 (standard deviation 6) years. In all, 48 left hemicolectomies, 68 right hemicolectomies, 14 transverse colectomies, 83 sigmoid colectomies, 32 segmental resections, 59 anterior resections, 75 abdominoperineal resections, 28 Hartmann's procedures, six total colectomies and 63 palliative operations were performed. All deaths in hospital occurring after surgery were considered as operative mortality. Age, antecedent hypertension, cardiac rhythm disorders, myocardial infarction, diabetes, renal insufficiency and chronic obstructive airways disease were considered risk factors. Postoperative bronchopneumonia, pulmonary embolism, myocardial infarction, anastomotic leakage with intra-abdominal sepsis and cerebrovascular accidents were considered postoperative life-threatening complications. The χ^2 test with Yates' correction was used for analysis of the data.

Results

Operative mortality

Of 476 patients, 64 postoperative deaths were observed between 1973 and 1986. Thus the overall operative mortality rate was 13·4 per cent. As shown in *Tables 1* and *2*, the principal cause was bronchopneumonia (27 per cent) occurring during the first postoperative week. The other aetiologies included: pulmonary embolism (17 per cent) which occurred during the second postoperative week, myocardial infarction (14 per cent) which occurred during the first three postoperative days, sepsis related to anastomotic leakage (14 per cent), most cases of which occurred during the third and fourth postoperative week, cerebrovascular accident (8 per cent) which also represented a late complication, multisystem organ failure related to preoperative peritonitis (5 per cent), all cases of which occurred during the first two postoperative days.

General risk factors

Preoperative status. One hundred and twelve patients (23·5 per cent) suffered from hypertension before their operation. Other pre-existing conditions were diabetes (27 cases, 5·7 per cent), chronic obstructive airways disease (30 cases, 6·3 per cent), previous myocardial infarction (24 cases, 5·0 per cent), renal insufficiency (7 cases, 1·5 per cent) and rhythm disorders (14 cases, 2·9 per cent). No significant differences in surgical mortality could be found between patients with none, one or two pre-existing diseases, operative mortality rate increased only in the small group of patients suffering from three preoperative disorders (*Table 3*).

No of preoperative diseases	No of patients	No. of deaths
0	295	36 (12·2)
1	137	16 (11·7) (χ^2 = 0·0001)*
2	36	7 (19) (χ^2 = 0·92, P < 0·4)*
3	8	5 (62) (χ^2 = 12·81, P < 0·0005)*
Totals	476	64 (13·4)

Values in parentheses are percentages. * Compared with patients having no preoperative diseases

However, two risk factors, chronic obstructive airways disease and antecedent myocardial infarction, were specifically correlated with an increase in postoperative life-threatening complications.

Age. The mean age of patients in the whole series was 68 years *versus* 74 years in the group of patients who died. The patients were divided into four age groups defined relative to the standard deviation of the whole series which was 6 years; there was no significant difference in mortality rate between patients younger than 62 years and those between 62 and 68 years However, there was a twofold increase in mortality in patients aged between 69 and 74 years (χ^2 = 6·78, P < 0·01) and a fourfold increase in those over 74 years (χ^2 = 24·66, P < 0·0005; *Table 4*).

In an attempt to dissociate age from the impact of pre-existing diseases, the surgical mortality was compared in two age groups with a similar preoperative status; for each definite preoperative risk factor, there was a higher mortality rate in the patients older than 69 years than in younger patients (*Table 5*).

Emergency procedures. Emergency surgery was performed in 62 patients (13·0 per cent): obstruction occurred in 44 patients and perforation in 18 patients. An increased operative mortality rate was associated with emergency procedures in comparison with elective procedures: 26 *versus* 11·6 per cent (χ^2 = 8·20, P < 0·005). This was related to a higher incidence of infection, anastomotic leakage (χ^2 = 9·61, P < 0·005) and bronchopneumonia (χ^2 = 5·44, P < 0·025) in these patients (*Table 6*).

Types and sites of resection. There is no significant difference in operative mortality between the different types of intervention, except for Hartmann's procedure which is associated with a surgical mortality rate of 35·7 per cent (28 patients, ten deaths). In our series, the Hartmann's procedure was performed only in poor-risk cases: among the 28 patients, 12 (43 per cent) were emergency procedures and 16 (57 per cent) were more than 74 years of age. The risk of anastomotic leakage was related to the site of anastomosis: four out of 102 right anastomoses (3·9 per cent) *versus* 31 out of 202 left anastomoses (15·3 per cent; χ^2 = 7·60, P < 0·01).

Specific risk factors and life-threatening complications

Bronchopneumonia occurred in 60 patients (12·6 per cent) with a 28 per cent mortality rate (17 patients). Patients with antecedent chronic obstructive airways disease had a higher incidence of postoperative bronchopneumonia (43 *versus* 10 per cent; χ^2 = 24·55, P < 0.0005) with a higher mortality rate (69 *versus* 17 per cent; χ^2 = 11·22, P < 0·001) than patients without lung disease.

Pulmonary embolism occurred in 11 patients (2·3 per cent) with a 100 per cent mortality rate. The patients with a past history of myocardial infarction had a higher incidence of postoperative pulmonary embolism than patients without this antecedent: 12 *versus* 2 per cent (χ^2 = 7·35, P < 0·01).

Myocardial infarction occurred in 14 patients (2·9 per cent) with a 64·3 per cent mortality rate (nine patients). There was a higher incidence (12·5 *versus* 2 per cent χ^2 = 4·95, P < 0·05) and a higher mortality rate (100 *versus* 54 per cent) of postoperative myocardial infarction in the group with a previous history of myocardial infarction.

Anastomotic leakage occurred in 35 patients (7·3 per cent) with a 26 per cent mortality rate (nine patients) related to sepsis and multisystem organ failure. Thirty-one patients had an anastomosis of the left colon and four had a right colon anastomosis.

Cerebrovascular accidents occurred in five patients (1·0 per cent) with a 100 per cent mortality rate. The mean age was 81 years; three of these five patients had a past history of

Table 4 *Surgical mortality in four age classes*

Age class (years)	No of patients	No. of deaths	Surgical mortality rate (%)
<62	140	7	5·0
62–68	123	9	7·3 (χ^2 = 0·28, P < 0·6)*

Totals	189	13	159	38

Morality rates given in parentheses. * Compared with patients ⩽68 years cerebrovascular disease and all five patients suffered with poorly controlled arterial hypertension.

Multisystem organ failure due to preoperative peritonitis occurred in three patients (0·6 per cent) with a 100 per cent mortality rate; the mean age was 81 years.

Changes in operative mortality

From 1973 to 1979, 44 patients out of 219 died (20·1 per cent); this was significantly different ($\chi^2=13{\cdot}06$, $P<0{\cdot}0005$) from the period 1980–86 during which there were 20 deaths in 257 patients (7·8 per cent). Between these two periods, the mean age was unchanged: 66 *versus* 63 years.

However, some other significant changes in the characteristics of the patients were found: (1) a diminished number of emergency procedures: 40 patients (18·3 per cent) from 1973 to 1979 *versus* 22 patients (8·6 per cent) from 1980 to 1986 ($\chi^2=9{\cdot}0$, $P<0{\cdot}005$); (2) a reduced incidence of pulmonary embolism: nine patients (4·1 per cent) from 1973 to 1979 *versus* two patients (0·8 per cent) from 1980 to 1986; (3) an improvement in the treatment of some postoperative complications. While the incidence of postoperative myocardial infarction and bronchopneumonia remained unchanged, the mortality rate associated with these complications was reduced from 100 to 38 per cent and from 55 to 15 per cent ($\chi^2=8{\cdot}63$, $P<0{\cdot}005$) respectively; the incidence and outcome of anastomotic leakage remain unchanged (*Table 7*).

Discussion

The operative morbidity and mortality rates related to colorectal surgery clearly depend on patient selection and underlying pathology (i.e. inflammatory process, diverticular disease or carcinoma)[1,2,7]. Our review from 1973 to 1986 includes 476 patients who underwent surgery exclusively for colorectal cancers.

The main causes of death in our series were similar to those reported in other studies[1,2,5]: myocardial infarction occurring during the first three postoperative days (14·1 per cent of postoperative deaths), bronchopneumonia mainly during the first postoperative week (27 per cent of postoperative deaths), pulmonary embolism mainly during the second postoperative week (17 per cent of postoperative deaths), anastomotic leakage and cerebrovascular accident mainly during the subsequent third and fourth postoperative weeks (14 and 8 per cent of postoperative deaths respectively).

Boyd *et al.*[7] found a relationship between the operative mortality rate and the number of pre-existing conditions rather than age as an isolated factor. We have found no significant difference between patients with none, one or two pre-existing disorders, but there was a higher risk of surgical mortality in older patients compared with younger patients. Life-threatening complications are correlated with specific risk factors rather than with the cumulative effect of any preoperative condition. For instance we found previous chronic obstructive airways disease was associated with a four times higher incidence of and mortality from postoperative bronchopneumonia; previous myocardial infarction was associated with a five times higher incidence of and a two times higher mortality from postoperative myocardial infarction and a seven times higher incidence of postoperative pulmonary embolism. These results confirm those reported by Garibaldi *et al.*[8], Jensen *et al.*[2] and Wightman[6].

There is a higher operative mortality rate and increased incidence of septic complications (bronchopneumonia and anastomotic leakage) associated with emergency procedures[7]; patients with anastomoses involving the left colon are particularly at risk[9–11].

Our improved results from 1980 to 1986 emphasize the importance of systematic antithrombosis prophylaxis by subcutaneous heparin, dextran or epidural anaesthesia[12], and early diagnosis and aggressive treatment of early postoperative complications (myocardial infarction and bronchopneumonia).

Surgical resection is the only curative therapy for colorectal cancers[1–5,13] and a more accurate estimation of operative risks should lead to a more rational perioperative management of poor-risk patients.

Table 6 *Postoperative complications in elective* versus *emergency procedures*

Complication	Elective surgery ($n=414$)	Emergency surgery ($n=62$)
Bronchopneumonia	46 (11·1)	14 (23) ($\chi^2=5{\cdot}44$, $P<0{\cdot}025$)*
Anastomotic leakage	24 (5·8)	11 (18) ($\chi^2=9{\cdot}61$, $P<0{\cdot}005$)*
Pulmonary embolism	9 (2·2)	2 (3)
Myocardial infarction	11 (2·7)	3 (5)

Percentages are given in parentheses. *Compared with elective surgery

Sixteen chronically constipated women (age range 20–66 years) and 29 healthy control subjects (age range 22–53 years) underwent neurophysiological assessment of the integrity of pelvic spinal reflexes. The results were compared with videourodynamic studies and multiport anorectal manometry combined with external anal sphincter electromyography. The neurophysiological assessment consisted of electrical stimulation of the dorsogenital nerve, while recording any evoked reflex activity in the external anal and urethral sphincters with concentric needle and surface electrodes. Of these constipated women, 75 per cent had absence of one or more evoked sacral reflexes (compared with 20 per cent of healthy controls, $P<0{\cdot}05$). Sensory thresholds and motor unit potentials in the external anal sphincter were similar in healthy and constipated women. Nine (56 per cent) constipated women displayed urodynamic abnormalities (increased bladder capacity, acontractile bladder and genuine stress incontinence). Only 38 per cent of constipated women perceived a desire to defaecate during rectal distension with up to 100 ml, compared with 95 per cent of normal subjects ($P<0{\cdot}0005$). Moreover, 73 per cent of constipated women did not relax the external anal sphincter during defaecation, compared with 12 per cent of controls ($P=0{\cdot}001$). Taking into account the possible significance of our data in relation to previous findings it is suggested that the integration of sensory information within the sacral cord may be impaired in chronic idiopathic constipation.

Keywords: Constipation, urology, sphincter

Patients with low spinal cord lesions usually suffer with difficulties in defaecation and micturition. Physiological studies in such patients reveal reductions in sensitivity of the rectum, and impaired reflex control of the external anal sphincter[1]. We were intrigued by the observation that patients with severe constipation often exhibit disturbances in anorectal[2,3] and urethrovesical[4] function that are similar to those seen in patients with low spinal cord lesions. Thus, the aim of this study was to investigate the role of disturbed spinal cord function in the aetiology of severe, chronic idiopathic constipation. This involved testing the integrity of evoked spinal reflexes relaying in the conus medullaris (S2–S4) and examining the relationship between these reflexes and anorectal and urethrovesical function.

Patients and methods

Subjects

Studies were carried out on 16 women, with a mean (s.e.m.) age of 40 (4) years (range 20–66 years), who were referred for investigation of intractable constipation of at least two years' duration. Intractable constipation was defined as the passage of fewer than two stools per week, despite ingestion of laxatives and dietary fibre. Four of these women were nulliparous, the remainder had had between one and four vaginal deliveries (median, two). Each patient had undergone full investigation, including large bowel radiology and thyroid function tests, to exclude local or systemic disease as an underlying cause of their symptoms. Five patients with previously normal bowel habit related the onset of their constipation to abdominal hysterectomy. Six of the 16 patients complained of urinary tract symptoms in addition to their constipation: three patients had urinary incontinence and increased frequency, two had increased frequency alone, and a further patient found it necessary to strain in order to micturate (*Table 1*).

Twenty-nine healthy asymptomatic women matched for age and parity acted as control subjects. Nineteen of these women underwent anorectal studies; ten consented to neurophysiological investigation.

This study received approval by the Sheffield Area Health Authority Ethical Committee; all subjects provided written informed consent.

Methods

Patients and controls underwent a series of investigations which included neurophysiological studies of evoked sphincter responses following electrical stimulation of the dorsogenital nerve, videourodynamic assessment of urethrovesical function, combined anorectal manometry and external anal sphincter electromyography, tests of rectal sensation, and defaecation studies using simulated stools.

Neurophysiological tests of spinal reflexes. Electrical stimulation of the dorsogenital nerve elicits a reflex contraction in the bulbocavernosus, external anal sphincter and urethral sphincter that is mediated via afferent and efferent fibres of the pudendal nerve relaying in the S2–S4 segments of the sacral cord[5,6]. Dorsogenital nerve stimulation combined with recordings of evoked electrical activity in the pelvic sphincters may thus provide a convenient and reliable means of assessing the innervation of the pelvic floor[7].

The Dantec Neuromatic 2000M equipment (Bristol, UK) was used for all neurophysiological studies, using the amplifier band width 20–2000 Hz.

Dorsogenital nerve stimulation was achieved by placing a bipolar, saline soaked, felt tipped surface electrode (Disa 13L22, Bristol, UK) between the labia minora in contact with the clitoris, with the cathode lying dorsally. Trains of square wave electrical stimuli, 0·2 ms duration, were applied at 2 Hz, the current being gradually increased until the subject felt a sensation of tingling. This procedure was repeated three times and the mean current required to reach the sensory threshold of the dorsogenital nerve was determined.

Electromyographic responses were recorded using a concentric monopolar needle electrode (Disa 13L50) inserted into the superficial

part of the external anal sphincter. In addition, electromyographic responses in the urethral sphincter were recorded using a bipolar platinum ring electrode (Disa 21L11) mounted on a 14 Fr gauge Foley catheter 1·5 cm proximal to the balloon. With the balloon inflated and pulled back against the bladder neck, the electrode lay within the urethral sphincter.

After determining the dorsogenital nerve sensory threshold, trains of up to 100 stimuli were applied at supramaximal level (3 × threshold level), most subjects found this part of the test uncomfortable, but tolerable. Electromyographic responses in both anal and urethral sphincters were processed using a built-in averaging facility, displayed on a storage oscilloscope and recorded on heat sensitive paper.

Latency times of any evoked activity in the anal and urethral sphincters were measured from the stimulus artefact to the take off point of the first detectable response

During the same investigation, motor unit potentials were recorded from the external anal sphincter. Four different needle insertions were used to record a total of 20 individual potentials (each representing a different site within the muscle). The duration, amplitude and number of phasic components of each action potential were assessed, using the 'trigger' and 'delay' facility of the recording equipment.

Videocystometry. Combined filling and voiding cystometrograms were performed with simultaneous radiographic screening. Two Vygon® (Ecouen, France) tubes, 1·2 mm diameter, were passed into the bladder, one tube was used to fill the bladder with 37 per cent Urografin® (Schering Health Care Ltd, Burgess Hill, UK) at room temperature, the other was filled with aqueous chlorhexidine acetate (0·02 per cent) and used to record total bladder pressure. A similar Vygon catheter was used to measure rectal pressure. Both manometric tubes were attached via Statham (California, USA) transducers to a Disa 2100 6-channel urodynamic system and chart recorder. Manometric recordings were reviewed in combination with video recordings of the radiographic images obtained during the study

The bladder was filled at approximately 50 ml/min, bladder function being assessed in accordance with the recommendations of the International Continence Society[8].

Combined anorectal manometry/external and sphincter electromyography. With the subject lying in the left lateral position, pressures were recorded in the rectum and at multiple sites in the anal canal using a multilumen perfused manometric probe (outside diameter 5 mm) that incorporated a rectal balloon[2]. The electrical activity of the external anal sphincter was recorded throughout the study using a bipolar wire electrode[2] inserted into the subcutaneous part of the external anal sphincter via a 23G hypodermic needle (B.D Microlance, Oxford, UK).

After measurement of basal and squeeze pressures[2], the rectal balloon was progressively distended with air in increments of 10 ml, up to a maximum volume of 100 ml, or until the patient found the distension intolerable. Distension was maintained at each volume for 60 s, and was followed by a rest period of at least a further 60 s. The following measurements were made: (1) the threshold distension volume required to initiate anal relaxation; (2) the lowest volume required to prevent recovery of the anal pressure to the preinflation value, (3) the threshold volume required to elicit electromyographic activity in the external anal sphincter; (4) the minimum rectal volume perceived by the subject; (5) the threshold volume required to produce the sensations of flatus and a desire to defaecate Next, subjects were asked to increase their intra-abdominal pressure by inflating a rubber party balloon. The existence of a reflex increase in external anal sphincter electromyographic activity was noted. Finally, the ability of subjects to evacuate two simulated stools of different shape and consistency was tested. A soft, sausage-shaped silicone prosthesis (volume 30 ml; 85 mm × 25 mm × 17·5 mm) simulated a normal stool, while a plastic sphere 18 mm in diameter attached to a metal beaded chain represented a hard pellety stool. Insertion was facilitated using lubricant KY Jelly (Johnson and Johnson Ltd., Slough, UK) and each object was pulled down so that its lower pole was resting against the innermost aspect of the anal sphincter. With the electromyographic electrode *in situ*, subjects were left alone on a commode and instructed to evacuate the simulated stool; the time taken to pass each object was noted

Statistical analysis

Data that appeared to be normally distributed were analysed using an unpaired Student's *t* test; the Mann–Whitney *U* test was applied to non-parametric data. Two-tailed Fisher's exact test and the χ^2 test were used when comparing the proportion of patients and controls who exhibited a particular feature

Results

Neurophysiological tests

Electrical stimulation of the dorsogenital nerve evoked responses from the external anal sphincter in nine of ten healthy controls, and from the urethral sphincter in nine of ten healthy controls. These responses were present in the external anal sphincter in only seven of 16 constipated patients, and in the urethral sphincter in only six of 16 constipated patients ($\chi^2=5\cdot56$ and $6\cdot95$ respectively, $P=0\cdot02$ and $P<0\cdot01$). All normal subjects, but only nine of 16 constipated women, had at least one recordable evoked response ($P<0\cdot05$).

Dorsogenital nerve sensory thresholds were similar in healthy controls and constipated patients. Reflex latency times were also similar in controls and those patients in whom an evoked response was present.

Motor unit potentials were within reported normal limits of duration and amplitude[9,10] in all controls and in 12 of the 13 constipated women tested. Only one patient showed abnormally prolonged polyphasic potentials suggestive of previous denervation.

Urodynamics

Nine (56 per cent) of the constipated women had evidence of concurrent bladder dysfunction[11] (*Table 1*). These included the six patients complaining of urinary tract symptoms, two asymptomatic patients with abnormally high bladder capacities[11]

Table 2 *Anorectal manometry results*

	Patient	Control	*P*
Maximum basal pressure (cmH_2O)	76 (9)	79 (9)	n.s.
Maximum squeeze pressure (cmH_2O)	130 (19)	147 (15)	n.s.
Internal anal sphincter relaxation-threshold (ml)	28 (7)	32 (9)	n.s.
Flatus threshold (ml)	29 (4)	18 (2)	0.02

Values are mean (s.e.m.); n.s., not significant

(1500 ml and 759 ml) associated with a large amount of residual urine and a further patient with genuine stress incontinence. Patients with abnormal urodynamics were significantly older (mean (s.e.m.) 50 (3) years) than those with normal urethrovesical function (mean (s.e.m.) 27 (4) years; $P=0·004$) and had more children (medians 2 *versus* 1, $P=0·04$). The five patients, who had had a previous hysterectomy (*Table 1*), all had urodynamic abnormalities ($P=0·03$, compared with the women who had not had a hysterectomy).

Eight of the nine patients with disordered urethrovesical function had at least one absent evoked sacral reflex; the pudendourethral reflex was unobtainable in six of these eight women. However, four of seven patients with normal urodynamic studies also had an absent pudendourethral reflex.

Combined anal manometry and external anal sphincter electromyography

All patients had evidence of anorectal dysfunction, in that rectal sensation was blunted and most patients were unable to relax the external anal sphincter during defaecation.

The minimum volume of rectal distension that elicited the sensation of flatus (*Table 2*) was significantly higher in constipated women than in normal controls (mean (s.e.m.) 28·7 (3·9) ml *versus* 17·8 (2·2) ml; $P=0·02$) and rectal distension up to a volume of 100 ml failed to initiate a desire to defaecate in 62 per cent of constipated patients, compared with only 5 per cent of healthy subjects ($\chi^2=13·2$, $P<0·0005$).

Although similar proportions of patients and controls successfully evacuated the simulated stools within 5 min, fewer patients were able to relax the external anal sphincter during attempted defaecation (plastic sphere 27 *versus* 88 per cent, $\chi^2=10·81$, $P<0·001$; silicone sausage 36 *versus* 71 per cent, $\chi^2=3·77$, $P=0·05$). Successful defaecation tended to take longer in the constipated group, although this difference did not reach statistical significance.

Basal and squeeze pressures were similar in both constipated and healthy women and there were no significant differences in the rectal volume required to either initiate relaxation of the internal anal sphincter or to elicit a relaxation that was sustained for 60 s (*Table 2*). External anal sphincter electrical responses to rectal distension were seen in 88 per cent of patients and all controls; threshold distension volumes were similar in both groups. External anal sphincter electrical responses to rises in intra-abdominal pressure were also seen in all patients and controls.

The results of combined anorectal manometry and electromyography were no different in the nine patients with an absent pudendoanal reflex compared with the remainder of the constipated women.

Discussion

Our results show that electrical stimulation of the dorsogenital nerve failed to evoke reflex activity in both the external anal sphincter and the urethral sphincter in 75 per cent of chronically constipated women compared with 20 per cent of normal individuals The observation that dorsogenital nerve sensory thresholds were normal and easily recorded in all subjects and motor unit potentials were of normal duration in all but one of the constipated women confirmed the accuracy of our stimulation and recording techniques and indicated integrity of both afferent and efferent limbs of the reflex, even in those patients who had had a hysterectomy. The absence of evoked responses would therefore suggest a localized anatomical or physiological disruption of neural signals transmitted through the sacral cord segments.

A similar conclusion was reached by Varma and Smith[7] who demonstrated prolonged pudendoanal latencies in association with normal sensory thresholds and normal motor unit potentials in 15 chronically constipated women, although complete absence of evoked external anal sphincter activity was noted in only two of their patients. These investigators suggested a conduction defect in the conus medullaris resulting from an occult sacral cord neuropathy, although such a lesion would have to be very localized, as most aspects of sacral cord function were spared. An alternative explanation for these findings is inhibition of the evoked reflexes by efferent signals from higher centres. Indeed, Bradley *et al.*[12] noted that it was possible for subjects to consciously inhibit electrically evoked sacral reflexes, although no subsequent reports have confirmed their experimental findings. Additional evidence which might suggest excessive central modulation of afferent input to the sacral cord is the highly selective nature of the anorectal sensory impairment found in constipated patients[2,3,7,13].

Is the absence of evoked sacral reflex activity a genuine reflection of disordered bladder and anorectal function? Our results appear to indicate that there is little correlation between the neurophysiological findings and disturbances in bladder and anorectal function, as most patients with absent evoked sacral reflexes had normal external anal sphincter electromyographic responses to rectal distension and increases in intra-abdominal pressure. However, as it is claimed that sacral reflex stimulation is a more sensitive method of identifying sacral cord dysfunction than simple electromyographic techniques[6,14,15], this technique may identify minor disturbances in sacral cord integration that do not necessarily manifest themselves as gross disturbances in function.

In conclusion, we have demonstrated that the majority of severely constipated women display abnormalities in the co-ordination of normal urethrovesical and anorectal function and our results suggest that the 'lesion' responsible for these changes lies within the central nervous system. It is possible that the underlying mechanism in these constipated women involves excessive supraspinal inhibition of normal sacral cord function, perhaps via a subconscious learned response, although further work would be necessary to establish this.

Paper accepted 26 January 1989

Announcement

USCI, Division of Bard Limited, have announced the launch of the Bard Surgical Scholarship Awards scheme.

The scheme is open to UK based registrars, senior registrars and research fellows, specializing in vascular surgery. Educational travel grants of £3000 (sterling) and £1000 will be awarded to candidates submitting the original research papers judged to be of the highest standard.

Further details and application forms may be obtained from: Surgical Product Manager, Bard Limited, Forest House, Brighton Road, Crawley, West Sussex, RH11 9BP, UK. Telephone number: 0293 27888.

The closing date for entries is 30 September 1989.

Br. J. Surg. 1989, Vol. 76, July, 752–755

Anal endosonography in the evaluation of perianal sepsis and fistula *in ano*

P. J. Law, R. W. Talbot,*
C. I. Bartram and
J. M. A. Northover*

*Departments of Radiology and *Surgery, St. Mark's Hospital, City Road, London EC1 2PS, UK*
Correspondence to:
Dr C. I. Bartram

Anal endosonography has been performed in 22 patients with fistula in ano *and perianal sepsis and compared with the operative findings. Using a special hard cone attachment to a radial 7 MHz probe the examination was well tolerated, rapid and generally accurate, detecting two unsuspected foreign bodies and all seven complicated fistula* in ano *preoperatively.*

Keywords: Imaging, anus, ultrasound

Surgery for fistula *in ano* is potentially difficult, and prior knowledge of a complicated fistula might be beneficial[1]. A complicated fistula has been defined as a fistula other than a superficial or simple intersphincteric fistula[2]. Clinical examination will identify an external opening and sometimes an internal opening. Subcutaneous induration and induration within the anal canal suggest possible sepsis and the direction of a track. However the exact anatomy is often difficult to determine. Probing a track may help but this is painful in the conscious patient and potentially dangerous[3].

Radiological delineation of fistulous tracks with water soluble contrast media has been described[4], but is considered of limited value[5]. Anal endosonography has the potential to image pathological abnormalities in the anal canal and perianal region. Pararectal abscesses and fistulae have been identified with a 5 MHz probe[6]. We have used a higher frequency 7 MHz probe, which provides greater near-field resolution, initially to establish the normal ultrasound anatomy of the anal canal and then to discover what features of fistula *in ano* can be visualized, so as to determine whether or not endosonography has a role in preoperative assessment.

Patients and methods

Twenty-two consecutive patients admitted to St. Mark's Hospital with a diagnosis of recurrent perianal sepsis or fistula *in ano* were studied prospectively. After clinical assessment, endosonography was performed by P.J.L. or C.I.B., without knowledge of the clinical findings. No bowel preparation was required. A Brüel and Kjær (UK) Ltd., Harrow, UK ultrasound scanner type 1846, with a 7 MHz rotating endoprobe, of 3-cm focal length was used. A specially designed hard sonolucent plastic cone, of maximum diameter 2 cm, was filled with degassed water to provide protection for the rotating probe and effective acoustic coupling in the anal canal (*Figure 1*). The lubricated cone was inserted with the patient in the left lateral position and serial images obtained on slow withdrawal.

Surgery was performed the following day by one of the consultant staff without prior knowledge of the sonographic findings.

The fistulae were classified by internal openings, muscle defects, scars, abscesses, either superficial, intersphincteric, supralevator or extralevator, and tracks with or without a horseshoe configuration. These criteria were used to compare the findings on endosonography and at surgery.

Results

Patients tolerated the procedure well with the exception of one patient with a Crohn's stricture at the anorectal junction.

The sonographic anatomy of the normal anal canal is shown in *Figure 2*. This was derived from the known anatomy of the rectum, correlation of surgical findings in other cases and some experimentation. The location of the external anal sphincter was confirmed at endosonography by identifying an electrode inserted into the muscle during electromyophysiological studies, and the intersphincteric plane by observing water injected into this space in an operative specimen.

The smooth muscle of the internal anal sphincter was clearly identifiable as a homogeneous hypoechoic band extending caudally to below the level of the anal valves, and lying in the same plane as the muscularis propria of the rectum. Striated muscle had a different acoustic texture and the external sphincter could be traced posterolaterally from the levator muscle down to the subcutaneous level as a broad band of mixed echogenicity with a prominent linear component. In male patients the external sphincter tapered anteriorly into two arcs that met in the midline, but in female patients the muscle was relatively deficient anteriorly adjacent to the vagina and perineal body. The internal sphincter was separated from the external sphincter by a narrow hyperechoic band of the intersphincteric plane. Directly in contact with the cone was the hypoechoic layer of mucosa. Between this and the internal

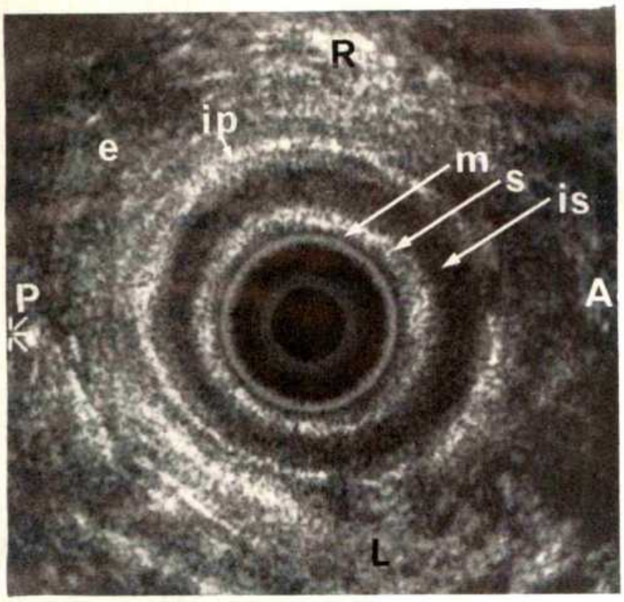

Figure 2 *Anal endosonography in upper anal canal showing orientation of images (P, posterior; A, anterior; R, right lateral; L, left lateral) and normal anatomy (m, mucosa; s, submucosa; is, internal sphincter; ip, intersphincteric plane; e, external sphincter)*

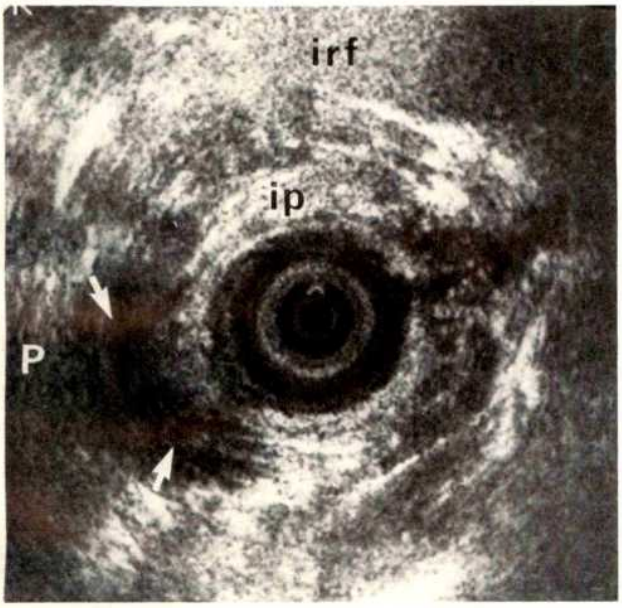

Figure 3 *Anal endosonography showing posterior abscess (arrows) with distortion of the adjacent external sphincter. Increased echoes seen in the ischiorectal fossa (irf). Note the widening of the intersphincteric plane (ip)*

sphincter was the echogenic submucosa, which became progressively denser and thicker caudally. Laterally at the edge of the field of view and deep to the external sphincter, bright echoes could be seen from reflections in the ischiorectal fossa (*Figure 3*).

Internal openings were visible as a break in the mucosal layer, with the site and level estimated from the position of the probe. Defects in the internal sphincter, caused either by previous surgery or sepsis, appeared as a loss in continuity in the circumferential ring of muscle. Infection within the intersphincteric plane caused widening and distortion of an otherwise narrow plane (*Figures 3* and *4*). Scars produced a homogeneous hypoechoic area, usually with a regular outline. Abscesses, although of similar hypoechogenicity were less homogeneous, containing areas of mixed echogenicity and more irregular in outline. Tracks created hypoechoic bands within the intersphincteric plane, and usually communicated with a cavity or scar. Tracks sometimes extended around the anal canal in a 'horseshoe' configuration (*Figure 5*).

Abnormalities of the external sphincter were difficult to define as associated changes in the intersphincteric plane altered the echo pattern of the adjacent muscle (*Figure 3*). Hypoechoic defects within the ring of striated muscle were interpreted as trans-sphincteric extension of inflammatory changes; this was supported by the surgical findings. The ischiorectal fossa was poorly defined, so that supralevator extension of such an abscess was difficult to recognize.

The surgical findings revealed a chronic abscess in 16 patients (two superficial, ten intersphincteric, two infralevator and two supralevator). A fistulous track was present in 12 (seven intersphincteric, five trans-sphincteric) and a horseshoe shaped track in four. Altogether seven of the fistulae were classified as complex.

The correlation between endosonography and surgical findings is shown in *Figure 6*. Endosonography identified the

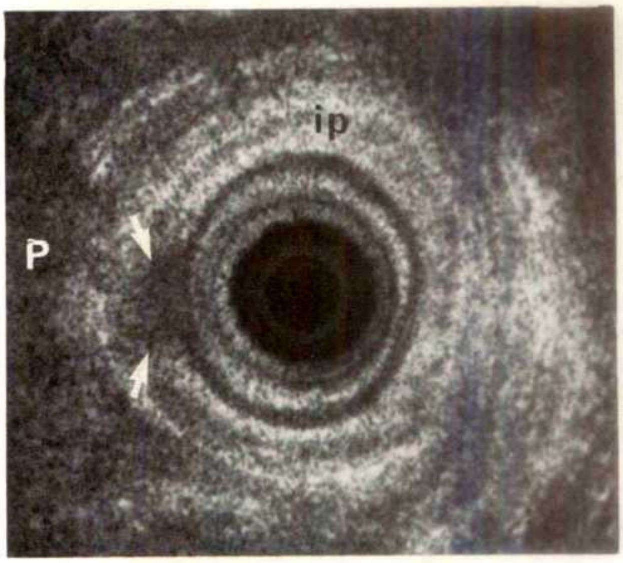

Figure 4 *Anal endosonography at level of anal valves demonstrating a posterior intersphincteric abscess (arrows) and adjacent muscle defect in the internal sphincter. Note also widening of the intersphincteric plane (ip)*

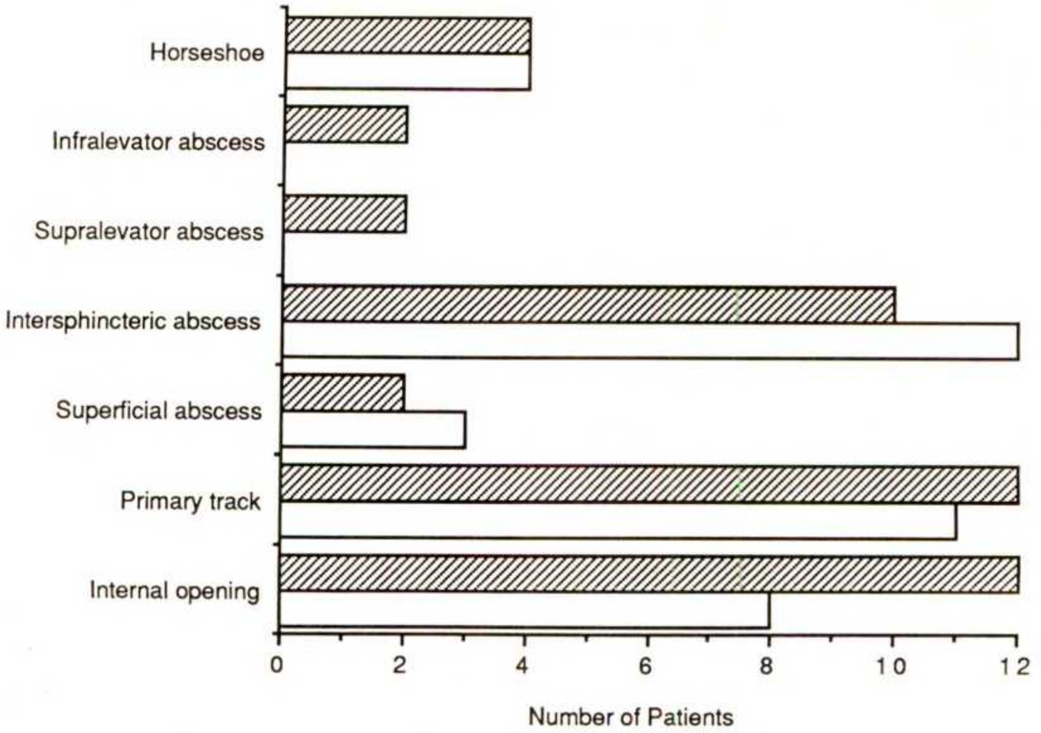

Figure 6 *Correlation between endosonographic and surgical findings in 22 patients with fistula* in ano; □, *ultrasound;* ▨, *surgery*

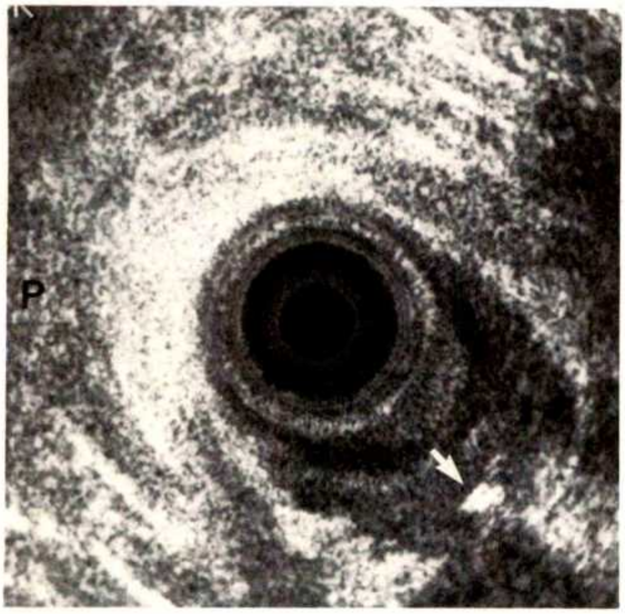

Figure 7 *Anal endosonography showing a bright focal lesion which proved to be a retained seton suture (arrow) within an anterolateral abscess cavity*

majority of the pathological changes except for infralevator and supralevator abscesses. The two patients incorrectly diagnosed as having intersphincteric abscesses, were found at surgery to have supralevator extensions not recognized by endosonography. In three patients small highly discrete echogenic foci were found and diagnosed as foreign bodies. Two of these were confirmed as such: one was a grape seed in an intersphincteric abscess and the other a buried seton suture (*Figure 7*). The third patient had a partially epithelialized track. Two superficial perianal abscesses were correctly diagnosed. The third proved to be a chronic Bartholin's abscess.

All of the seven patients with surgically proved complicated fistulae were correctly identified preoperatively.

Discussion

The sonographic anatomy of the normal rectum has been investigated extensively in relation to determining the depth of tumour invasion[7–10]. Five basic ultrasound layers have been described in the rectum. There are two hyperechoic layers consisting of the submucosa and serosa, interleaved with three hypoechoic layers of the mucosa, muscularis mucosa and muscularis propria. Some investigations of anal canal anatomy have been undertaken with 4 or 5 MHz transrectal probes in fistulae[6] and anal cancer[11], which support our description of the internal anal sphincter. Our understanding of the endosonographic anatomy has been built up from experience in rectal endosonography, extrapolation of the known appearances of various layers, correlation with pathological findings and some experimentation. The validity of the description offered is supported by complete agreement between the anatomical location of abnormalities predicted and the findings at surgery.

Two aspects of the apparatus were found to be critical for accurate examination of the anal canal. The 7 MHz probe has considerably improved resolution in the near field, and was essential to show subtle changes. The hard cone has been designed specifically for use in the anal canal. Endosonography was attempted with the standard rectal balloon, but the rotating probe tended to catch and tear the balloon as it was manipulated in the anal canal. To avoid this, it was necessary to fill the balloon with large volumes of water forcibly to dilate the anal canal, which caused anatomical distortion and discomfort. The hard cone is no more traumatic than digital examination, and keeps the canal open with its walls parallel for true anatomical presentation.

Supralevator extension of an abscess and disease within the ischiorectal fossa were not identified endosonographically as image definition in this area was poor. There are perhaps two reasons for this. Ultrasound requires acoustic coupling to obtain any picture and, as the probe gives a radial field, only the immediate structures within a radial plane along the canal will be imaged with the hard cone attachment. Some improvement may be possible by using the balloon attachment designed for rectal examination, as the balloon would maintain acoustic contact in the ampulla to reveal any lesion in this plane. Another problem is lack of penetration of the ultrasound beam. Lesions lying deep to the external sphincter may be outside the field of view.

Identification of internal openings was not wholly successful, possibly because of the proximity of the mucosa to the probe, so that it was not within focal range. Although fistulae with a high internal opening have been defined as being complicated[12], most openings occur at the level of the anal valves regardless of complexity. Intersphincteric disease and trans-sphincteric tracks were correctly identified in most patients. Differentiation between abscess cavities, granulated tracks and scars was sometimes difficult but has improved with experience. Straight tracks were easily identified, but smaller and oblique tracks were more difficult to image. There was good correlation between endosonography and surgery in identifying horseshoe extensions and in detecting foreign bodies.

Endosonography requires experience, but is a simple technique that is inexpensive and well tolerated by the patient. In this study, all seven of the fistulae considered to be complex at surgery were identified preoperatively. Such knowledge may influence operative technique and would be of particular help to those with limited experience in this field of surgery.

Professor N. O'Higgins

To assess the effect of mechanical bowel preparation on anastomotic integrity after low anterior resection, 36 mongrel dogs were randomized to have low anterior resection with or without mechanical bowel preparation. All dogs received prophylactic antibiotics and anastomotic integrity was assessed on the ninth postoperative day by barium enema, inspection of anastomoses for defects after careful excision at laparotomy, and anastomotic bursting pressures. Bursting pressures were significantly higher ($P<0{\cdot}005$) *in the group with bowel preparation. Anastomotic defects were present in 13 per cent of animals with bowel preparation and 47 per cent without bowel preparation* ($P=0{\cdot}057$)*. Pelvic abscess and death from peritonitis occurred in 6 per cent of the group with bowel preparation and 29 per cent of the unprepared group. Mechanical bowel preparation significantly enhanced anastomotic integrity and reduced complications in this model.*

Keywords: Rectum, surgery, surgical technique, animal experiment

A recent study by Irving and Scrimgeour has questioned the need for mechanical bowel preparation when performing colorectal resection with primary anastomosis[1]. In a series of 72 consecutive colectomies with primary anastomosis where all preoperative and perioperative mechanical preparation was omitted and the patients were treated by a single peroperative intravenous dose of cefuroxime and metronidazole, the authors reported a clinically apparent anastomotic dehiscence rate of zero, a wound infection rate of 8·3 per cent, and an operative mortality rate of 2·7 per cent. However, only seven patients in the series had elective low anterior resections, the area in large bowel surgery in which anastomotic dehiscence is most commonly observed. Goligher and associates reported anastomotic dehiscence in 18 of 26 patients (69 per cent) submitted to low anterior resection when dehiscence was sought by digital and sigmoidoscopic examination[2]. Seven of these patients, one of whom died, had overt faecal fistulae discharging on to the abdominal wall or into the vagina.

The aim of the present study was to examine the effect of mechanical bowel preparation on anastomotic integrity following low anterior resection in dogs.

Materials and methods

Animals

Thirty-six mongrel dogs were randomized to two groups: one with and one without bowel preparation. The average weight and male:female ratio in both groups were similar. All were fed Febo® (Quaker Latz, Euskirchen, FRG) dog food and had water *ad libitum*. Dogs were fasted from midnight on the day of the operation and the bowel preparation group had fluids only for 48 h preoperatively. Twenty-four hours preoperatively, animals in the bowel preparation group were given sodium picosulphate 10 mg, magnesium oxide 3·5 mg and citric acid 12 g (Picolax®, Nordic Pharmaceuticals Ltd., Feltham, UK) orally as a single dose. Postoperatively all animals were given water only for 24 h and full diet as tolerated thereafter.

Animal model

Dogs were anaesthetized with sodium thiopentone (5 mg/kg), intubated with a cuffed endotracheal tube and ventilated with nitrous oxide, halothane and oxygen. The bowel preparation group had on-table water enemas using a cuffed polyethylene tube passed per rectum in a closed system until clear. All dogs received a single dose of prophylactic antibiotics (cefuroxime 250 mg and metronidazole 250 mg, intravenously) at induction of anaesthesia. Abdomens were shaved and prepared with Betadine® (Napp Laboratories Ltd., Cambridge, UK). Laparotomies were carried out through a midline incision. The left colon and rectum were mobilized and a segment of bowel from the caudal mesenteric artery (inferior mesenteric) to mid-rectum was excised (*Figure 1*). Bowel ends were cleaned with chlorhexidine swabs and a tension free anastomosis performed using an inverting, single-layered technique with interrupted 2/0 Nurolon® (Ethicon Ltd., Edinburgh, UK)[3]. Laparotomy incisions were closed with 1/0 continuous nylon and skin with 3/0 nylon. No drains were used. All operations were carried out by the same surgeon and assistant. All animals received 1 litre of normal saline intravenously at operation.

Assessment of anastomotic integrity

All animals were killed on the ninth postoperative day by overdose with pentobarbitone sodium (60 mg/kg), and anastomotic integrity was assessed by single contrast barium enema, inspection of anastomoses for defects after careful excision at laparotomy, and anastomotic bursting pressures. Bursting pressures were carried out on a standard length of bowel after the faecal content had been milked out and perianastomotic tissue adherent to the anastomosis removed. The proximal end of the anastomosis was connected to an air-injecting perfusor and air was perfused at a constant rate by means of a polyethylene tube. The distal end was connected to a 0–300 mmHg pressure transducer and the pressures were recorded. The bowel was inflated under water and the point at which air bubbles appeared from the anastomosis taken as the bursting pressure.

Statistical analysis

Comparison of anastomotic dehiscence rates in both groups on barium enema, and inspection, was made by Fisher's exact test. Comparison of bursting pressures in both groups was made by the Mann–Whitney *U* test.

Results

In three of the 36 dogs anastomotic integrity was not evaluated because the animals died in the perioperative period. One was a preoperative death secondary to aspiration pneumonia which occurred when the animal was receiving Picolax. The other two were postoperative deaths: a death due to anaesthesia and a death due to dehiscence of the laparotomy incision on the third postoperative day. The anastomosis in the latter was clinically intact. Thus 33 dogs were evaluable, 17 without and 16 with bowel preparation.

Four dogs (23 per cent) with no bowel preparation and one (6 per cent) with bowel preparation had anastomotic defects

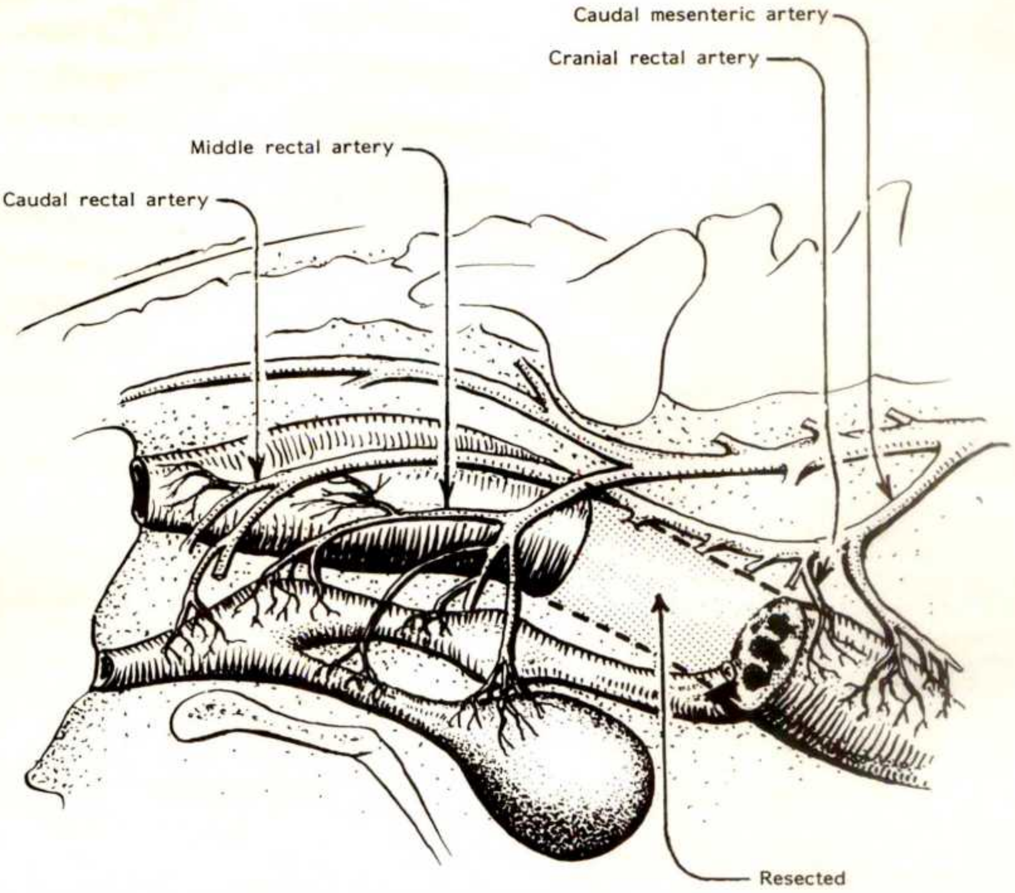

Figure 1 *Lateral view of the rectum and anal canal of a dog indicating extent of bowel resection*

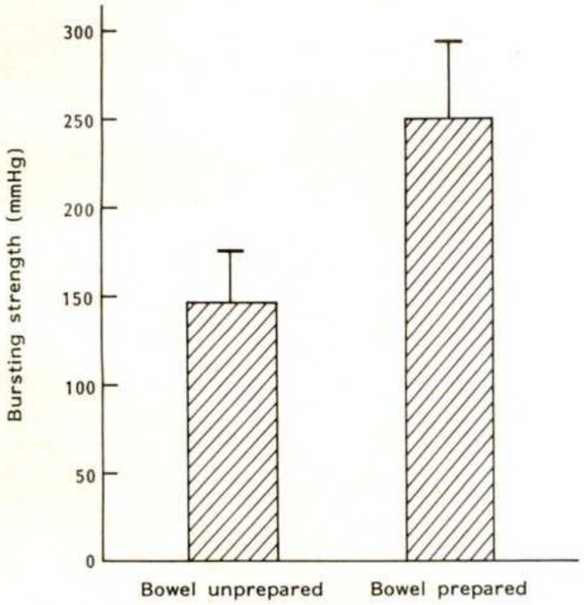

Figure 2 *Anastomotic bursting pressures in both groups (pressures were measured on all anastomoses)*

on barium enema (P = n.s.). Eight (47 per cent) without and two (13 per cent) with preparation had anastomotic defects on inspection of anastomoses after their removal from the peritoneal cavity at laparotomy ($P = 0.057$). No anastomosis was damaged while performing this procedure. Anastomotic bursting pressures were significantly higher ($P < 0.005$) in the group with bowel preparation (*Figure 2*).

There were two deaths secondary to peritonitis and three pelvic abscesses in the unprepared group. There was one death secondary to peritonitis in the prepared group. All deaths and abscesses were associated with anastomotic dehiscence. Cultures from abscesses and peritoneal fluid confirmed colonic microflora in all cases.

The extent of faecal load in the colon at the time of operation was assessed for each unprepared dog. This was graded clinically in increasing amount from +1 to +4 (*Table 1*). While there was no significant correlation between anastomotic dehiscence and faecal load both animals that died had +4 faecal load at the time of operation. Faecal load was minimal (+1) in all 16 prepared dogs.

The effect of contamination (macroscopic spillage) at operation on anastomotic dehiscence and complications was

Table 1 *Effect of faecal load on anastomotic dehiscence and complications in the 17 dogs with no bowel preparation*

Faecal load	Number	Anastomotic dehiscence	Pelvic abscess	Deaths
+	3	2	2	—
++	5	1	—	—
+++	4	2	1	—
++++	5	3	—	2

Table 2 *Effect of contamination at operation on anastomotic dehiscence and complications*

Group	Number	Anastomotic dehiscence	Pelvic abscess	Deaths
Bowel prepared	7 (44)	1	0	1
Bowel unprepared	3 (18)	3	1	1

Values in parentheses are percentages calculated from the total number of dogs in each group also assessed (*Table 2*). This occurred more commonly in the prepared group but was less likely to be associated with anastomotic dehiscence: 14 per cent compared with 100 per cent in the unprepared group (P=n.s.).

Discussion

Mechanical bowel preparation was shown to increase anastomotic bursting pressures significantly and reduce anastomotic dehiscence rates and related complications after low anterior resection in mongrel dogs. The model of low anterior resection in dogs is analogous to that of low anterior resection in man in many respects. The microflora of the large intestine in both are similar and experimental intra-abdominal sepsis using intestinal microflora in dogs is almost completely prevented by use of a cephalosporin or metronidazole[4]. The blood supply and anatomical relationships of the rectum and sigmoid are also similar in the dog and man[5].

The rate of anastomotic dehiscence after colorectal resection with primary anastomosis varies widely among reported series[1,6–8]. It is significantly higher after anterior resection of the rectum compared with intraperitoneal enteric anastomoses[6] and higher again when low anterior resection is compared with high anterior resection[2]. There are many causes of anastomotic dehiscence. However, in the Large Bowel Cancer Project[6], a prospective study looking at dehiscence rates in almost 1500 patients undergoing colorectal resection with primary anastomosis, the most important significant factor was the variability in dehiscence rates among different surgeons.

There are few data available in the literature on the effect of mechanical bowel preparation on anastomotic dehiscence. Hughes, in a study of 46 patients who underwent bowel preparation and 51 who did not, found no difference in wound infection rates, peritonitis or deaths between the groups in a personal selected series[9]. Goligher and associates, examining the influence of gross faecal loading on anastomotic dehiscence after both low and high anterior resection, showed a higher incidence of dehiscence in patients with colonic loading[2]. This difference, however, was not quite statistically significant and the patients with gross faecal loading were chosen from a group in which mechanical bowel preparation had failed.

The mechanism of increased anastomotic dehiscence and reduced bursting strengths associated with omission of bowel preparation in this study is difficult to explain. It is noteworthy that the three animals in the unprepared group with faecal contamination all had anastomotic defects. It is well established in experimental studies that intraperitoneal sepsis or placement of faeces at or near an anastomosis increases anastomotic dehiscence rates[10]. Similarly in clinical studies faecal soiling at operation is associated with an increased incidence of anastomotic dehiscence[2,7,11]. Infection causes a reduction in collagen at the anastomosis[10]. This may result from excessive collagenase production or from imbalance between collagenase and controlling tissue inhibitors[12].

Mechanical bowel preparation is shown to enhance anastomotic integrity significantly after low anterior resection. While these data cannot be extrapolated directly to low anterior resection in humans it would seem prudent to continue using bowel preparation in this situation while awaiting results from further clinical and experimental studies on this subject.

Clinicopathologic study of early stage esophageal carcinoma

Keizo Sugimachi, MD, FACS, Shinji Ohno, MD, Hiroyuki Matsuda, MD, Masaki Mori, MD, Hideo Matsuoka, MD, *and* **Hiroyuki Kuwano, MD,** *Fukuoka, Japan*

*As part of a consecutive series of 370 patients who underwent subtotal esophagectomy because of carcinoma of the thoracic area of the esophagus, between January 1965 and July 1988, in the Second Department of Surgery, Kyushu University Hospital, 42 patients (11.4%) with early stage esophageal carcinomas confined to the intraepithelium, mucosa, or submucosa were studied clinicopathologically. Of these 42, 26 (61.9%) had symptoms; slight dysphagia or chest discomfort was the most common symptom. The remaining 16 (38.1%) had no subjective symptoms. Endoscopic examination proved to be more useful than barium studies. Lugol-combined endoscopy was most effective in detecting the presence and spread of small malignant lesions of the esophagus. At the time of surgery, six patients with submucosal carcinoma of the esophagus had lymph node metastasis, and five died of recurrence. Described herein are the diagnostic features, clinicopathologic characteristics, and long-term results of these 42 patients with early stage, and 328 patients with advanced, carcinomas of the esophagus, detected and surgically treated in our clinics. (*SURGERY *1989;105:706-10.)*

From the Department of Surgery II, Kyushu University, Fukuoka, Japan

AS ESOPHAGEAL CANCER rapidly metastasizes to other organs through hematologic and lymphatic routes, early treatment, including surgery and irradiation, has to be given. In Japan, approximately 40% of gastric cancers may be detected in the early stage, when the carcinoma is confined to the mucosa or submucosa.[1, 2] Only 2.5% (7/277) of resected esophageal carcinomas, however, were early stage cancers.[3] Between January 1965 and July 1988, 370 patients with carcinoma of the thoracic part of the esophagus underwent subtotal esophagectomy in the Second Department of Surgery, Kyushu University Hospital. Of these, 328 (88.6%) had advanced cancer and 42 (11.4%) early stage esophageal carcinomas; that is, the depth of cancer invasion was confined to the epithelium, the lamina muscularis mucosae, or to the submucosa. Feasible approaches to early detection, the clinicopathologic characteristics, and the long-term results of these 42 early stage esophageal carcinomas are discussed.

PATIENTS AND METHODS

Between January 1965 and July 1988, 587 Japanese patients with carcinoma of the thoracic esophagus were admitted to the Second Department of Surgery of Kyushu University Hospital. Of these, 370 each underwent subtotal esophagectomy, the rate of resectability being 63.0%. In most patients a one-stage operation was performed: subtotal esophagectomy and dissection of the lymph nodes were carried out via right thoracotomy; the esophagus was reconstructed with a gastric tube via the antesternal route.[4]

Of these 370 patients, 42 (11.4%) had early-stage carcinoma confined to the intraepithelium, mucosa, or submucosa (Table I) that fell under a category of Tis and T1 by new TNM classification.[5] The other 328 (88.6%) had advanced esophageal cancer.

All the resected specimens, including the lymph nodes, were histopathologically examined, and the early and advanced-stage cancers were compared as to their characteristics, mortality rates, and postoperative complications.

The survival rates were estimated with use of the method of Kaplan and Meier,[6] and other statistical analyses were performed with the χ^2 test.

RESULTS

Efficacy of Lugol-combined endoscopy in detecting early stage esophageal carcinoma. Between 1965 and 1984, only 19 of the 270 (7.0%) surgically treated patients had early stage cancers. In all early stage carcinomas detected before 1985, the depth of invasion was limited to the submucosa.

Legend: sq ca, Squamous cell carcinoma.

Since 1985, we have used Lugol-combined endoscopy,[7-9] with a remarkable increase in detection of the cancer at an early stage. From January 1985 to July 1988 surgery was done on 100 patients with esophageal cancer, and of these, 23 (23%) had an early stage cancer. In patients seen during these years, if there were doubts about the integrity of the mucosal surface, we instilled about 20 ml of 2% Lugol's solution via a polyethylene tube, under direct vision, and biopsy specimens were taken from the unstained area. In none of the 270 patients treated in the 20-year period from 1965 to 1984 was detection made at the stage at which cancer invasion was limited to the epithelium or the lamina muscularis mucosae. Lugol-combined endoscopy made feasible detection of esophageal cancer at the stage at which it was still confined to the epithelium (1/100, 1.0%) or the lamina muscularis mucosae (6/100, 6.0%). The detection rate of esophageal cancer limited to the submucosa also increased, compared with the earlier periods: 16 of 100 (16.0%) of the patients surgically treated between January 1985 and July 1988 had cancer limited to the submucosa.

Macroscopic classification and location of early stage esophageal carcinoma. The gross appearance of the 42 early stage cancers was macroscopically classified into three types (Fig. 1): elevated, superficial, or depressed. As shown in Table II, all of the cancers limited to the epithelium or lamina muscularis mucosae were of the superficial type. On the other hand, in patients with submucosal cancer there were 15 patients with elevated, 10 patients with superficial, and 10 patients with the depressed types, respectively.

Table II. Macroscopic classification of early stage esophageal carcinoma

	Depth of invasion			
Type	*ep*	*mm*	*sm*	*Total (%)*
I (Elevated)	0	0	15	15 (35.7)
II (Superficial)	1	6	10	17 (40.5)
III (Depressed)	0	0	10	10 (23.8)
Total	1	6	35	42 (100)

Legend: ep, Invasion limited to the epithelium; mm, invasion confined to the lamina muscularis mucosae; sm, invasion confined to submucosa.

Of the 42 early stage esophageal cancers, the majority (26, 61.9%) were located in the middle third of the esophagus; in 2 (4.8%) and in 14 (33.3%) the upper third and lower third of the esophagus were involved, respectively.

Symptoms of early stage esophageal carcinoma. Of the 42 patients with early stage esophageal carcinoma, seven had cancer confined to the epithelium or lamina muscularis mucosae. None of these seven arrived with subjective symptoms. On the other hand, of 35 patients with submucosal carcinoma, 26 (74.3%) had subjective symptoms, such as slight dysphagia (13 patients), chest discomfort (11 patients), or pyrosis (2 patients). In 6 of the 16 patients with no symptoms, early stage esophageal carcinoma was detected at the time of endoscopic follow-up for gastric ulcer. In the other 10 patients with no symptoms, esophageal carcinoma was detected at the time of endoscopic screening for gastric cancer. Of 328 patients with advanced carcinoma, only three (0.9%) had no symptoms. The upper gastrointestinal series revealed esophageal carcinoma.

Although 23 of the 35 submucosal carcinomas were initially diagnosed by means of an upper gastrointestinal series, this type of examination did not lead to detection of mucosal or intraepithelial esophageal carcinoma. At that level of invasion, the carcinomas were initially diagnosed by means of Lugol-combined endoscopy and biopsy; the subsequent upper gastrointestinal series did not lead to an accurate diagnosis.

Results of histopathologic examination. Of the 42 early stage esophageal carcinomas, 6 (14.3%), 24 (57.1%), and 12 (28.6%) were well-, moderately, and poorly differentiated squamous cell carcinomas, respectively. There was no evidence of lymph node metastasis in the seven patients with intraepithelial or mucosal carcinoma, and all malignant tissue was thought to have been completely excised. Among the 35 patients with submucosal carcinoma, however, 15 (42.9%) manifested vessel invasion, and in six (17.1%) there

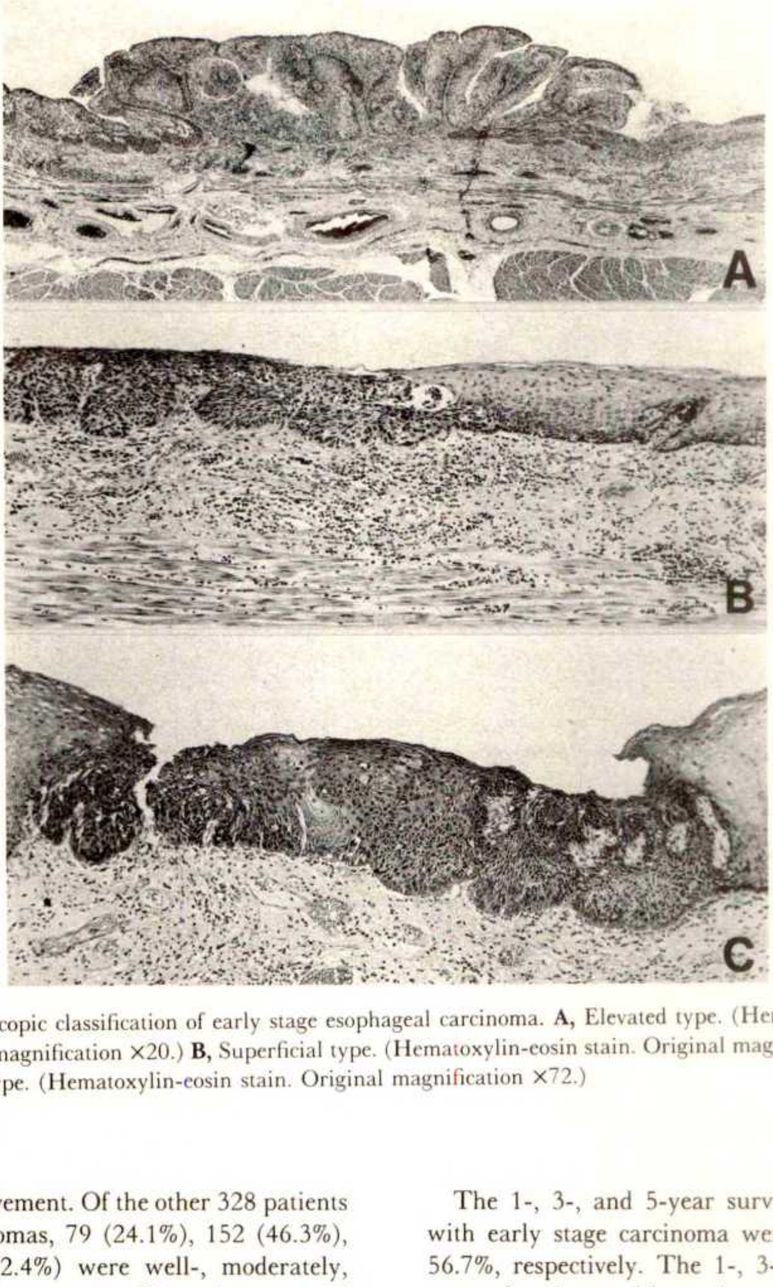

Fig. 1. Macroscopic classification of early stage esophageal carcinoma. **A,** Elevated type. (Hematoxylin-eosin stain. Original magnification ×20.) **B,** Superficial type. (Hematoxylin-eosin stain. Original magnification ×72.) **C,** Depressed type. (Hematoxylin-eosin stain. Original magnification ×72.)

was lymph node involvement. Of the other 328 patients with advanced carcinomas, 79 (24.1%), 152 (46.3%), 89 (27.1%), and 8 (2.4%) were well-, moderately, poorly differentiated squamous cell carcinomas, and adenocarcinoma, respectively.

Outcome. The surgical mortality rates (death within 30 days of surgery) of patients with early esophageal carcinoma and patients with advanced cancer were 2.4% and 5.2%, respectively. Of the latter group, 8 died of pneumonia, 4 of anastomotic leakage, and 2 of heart failure (Table III). All of these deaths occurred in patients surgically treated before 1983; since then, the operative mortality has been nil, mainly because of improvements in nutritional support (intravenous hyperalimentation) and improved respiratory and circulatory care.

The 1-, 3-, and 5-year survival rates for patients with early stage carcinoma were 91.3%, 56.7%, and 56.7%, respectively. The 1-, 3-, and 5-year survival rates of patients with carcinoma invading the proper muscle layer or deeper were 52.9%, 23.0%, and 15.6%, respectively (Fig 2). Thus, prognosis of patients with early stage carcinoma was superior to those with advanced carcinoma, with a statistically significant difference ($p < 0.01$).

In this study there were six patients with early stage carcinomas, yet lymph node involvement was evident at the time of surgery. Of these six patients, five died of recurrence. For 25 patients with no lymph node involvement or vessel invasion, the 5-year survival rate was 79.2%. On the other hand, the 5-year survival rate was only 24.7% for 17 patients with either or both

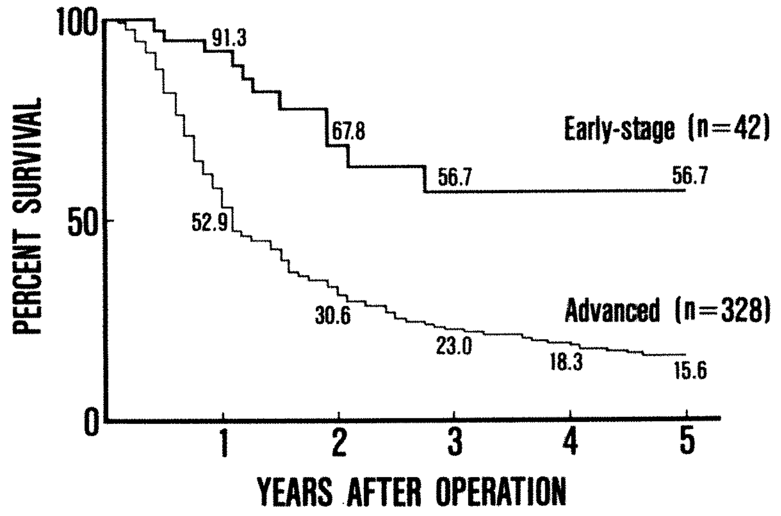

Fig. 2. Actuarial survival rates of surgically treated patients with early stage and advanced esophageal carcinoma. The difference between the two groups is statistically significant ($p < 0.01$).

Table III. Mortality and postoperative complications

	Early stage carcinoma *n = 42 (%)*	*Advanced carcinoma* *n = 328 (%)*	
Mortality	1 (2.4)	17 (5.2)	
(Death within 30 days after surgery)	Pneumonia 1	Pneumonia	8
		Anastomotic leakage	4
		Heart failure	2
		Liver failure	1
		Peritonitis	1
		Cerebral thrombosis	1
Postoperative complications			
Lung	6 (14.3)	83 (25.3)	
Liver	2 (4.8)	25 (7.6)

Others	5 (11.9)	29 (8.8)	

factors. The 5-year survival rates for patients with advanced cancer with and without these factors were 12.7% (264 cases) and 27.8% (64 cases), respectively. The survival of patients with early cancer and lymph node involvement and/or vessel invasion was about the same as that of those with advanced cancer without lymph node involvement. Thus, the prognosis of patients with early stage carcinoma with vessel invasion and/or lymph node involvement is far from satisfactory.

DISCUSSION

Matthews et al.[10] reported that in Western countries the overall 5-year survival rate of 4680 patients with esophageal carcinoma treated with current methods was a disappointing 5%. Hence, early detection and adequate treatment require intensive research.

Since 1985, we have made use of Lugol-combined endoscopy, apparently first described by Brodmerkel in 1971. Application of this Shiller's test led to a marked increase in the early detection of esophageal carcinoma, when the invasion was confined to the intraepithelial, mucosal, or submucosal layer. Carcinomatous lesions contain no glycogen and thus remain unstained. The extent of the lesion may easily be determined, even by gross inspection.[7,9] Of the 270 patients we surgically treated between 1965 and 1984, a malignancy at the stage of intraepithelial or mucosal invasion was not detected. Since we began to use Shiller's test, however, we detected cancers limited to the epithelium in 1 of 100 patients treated during that period, and six patients were treated before the invasion had gone beyond the lamina muscularis mucosae. Therefore Lugol-combined endoscopy and endoscopic biopsy are indeed effective diagnostic tools available for the detection of small cancers of the esophagus. None of these lesions was evident on x-ray films.

Koehler et al.[11] defined early esophageal carcinoma as tumors 3.5 cm or less in length that involve only one wall of the esophagus, as viewed radiographically. The Japanese Society for Esophageal Disease defines superficial esophageal carcinoma as lesions in which infiltration does not go beyond the submucosal layer,[12] a definition based on postoperative pathologic findings. In our series of 370 patients who underwent surgical therapy for esophageal cancer, 42 (11.4%) were thus classified as cases of superficial esophageal carcinoma, or as Tis and T1 carcinoma, according to the new TNM classification.[5]

The operative mortality of patients undergoing esophageal surgery by a specialist trained to do this surgery now stands at less than 7%.[13, 14] Factors that reduce postoperative complications and operative mortality are (1) nutritional support, (2) perfect anastomosis, and (3) postoperative respiratory and circulatory care. In cases of advanced esophageal cancer, radical operation—including extended lymph node dissection and combined resection of other organs—has been recommended.[15, 16] As a result, the operative mortality rate in patients with advanced carcinoma was higher (5.2%) than in patients treated because of early stage carcinoma (2.4%).

A characteristic histopathologic feature of early esophageal carcinoma, compared with other carcinomas of the gastrointestinal tract, seems to be an unexpectedly high incidence of vessel invasion and lymph node involvement, although these lesions are considered to be relatively early ones. Other investigators[17, 18] reported that the 5-year survival for early esophageal carcinoma without lymph node involvement was 80% to 90%. The prognosis, however, of patients with early cancer with lymph node involvement was as poor as that of those with advanced cancer. Among our 42 patients with early stage esophageal carcinomas, 17 (40.5%) had lymph node involvement or vessel invasion or both, and the 5-year survival was only 24.7%. Therefore our results suggest that the degree of malignancy of esophageal cancer cells is high, even at the early stage. If patients survive without a recurrence, they may be expected to enjoy a life of good quality.[19] Therefore we wish to stress that efforts must be made to detect esophageal carcinoma at the earliest possible stage. Lugol-combined endoscopy facilities detection of minute malignant lesions of the esophagus.

We thank M. Ohara for critical comments.

Need for surgical wound dressing

Sir

I read with interest the paper by Chrintz *et al.* (*Br J Surg* 1989; **76**: 204–5). It is certainly not harmful to leave a sutured surgical wound uncovered; the wound can be more easily examined, costs in material and nursing hours are reduced and the patient can more easily move and carry out his personal hygiene.

Why apply a dressing to the wound during the first 24 hours? As long ago as 1951, following the example of my Master, Professor Georges Thomeret, I never have applied a dressing in the operating room on sutured surgical wounds, wherever they were located. All my fellows and students are taught to do so and in the course of time many surgical wounds have been left completely undressed. Of course, this method implies a perfectly sutured wound, free of any drop of blood that might soil either linen or bed sheets.

Surgical glove perforation

Sir

In the February 1989 issue Dr A. J. Hamer referred to his fine device for discovering holes in surgical gloves (*Br J Surg* 1989; **76**: 206). What he states is undoubtedly correct and his device is probably worthwhile. It is re-invented every few years, but I believe that we originally described it in 1959. Our description has been referred to rather frequently. A somewhat similar device was also described in about 1960 in the Canadian literature as well as in the *Lancet* in 1958.

Unfortunately, in the July issue of the *American Journal of Surgery* in 1972, Joseph Miller showed that surgical rubber gloves become permeable to an electric current after a period of time which varies from 30 min upwards (this has recently been confirmed in the UK). Fletcher Miller and his associates also described this instrument as a new invention in 1966, but, unfortunately, Joseph Miller's problem has not yet been overcome and so I would warn users of such an instrument of false results which may cause them problems.

Author's reply

Sir

I am grateful for Mr Beck's comments concerning my device. The principle of monitoring the drop in electrical resistance across a rubber glove due to a glove puncture is indeed not new, but the devices previously described all depended upon currents within the milliampere range for such detection[1–3]. The operator would also have to stop operating for a moment to dip his hands into a bowl of saline. British Standard BS5724 only allows currents of 100 μA or less to be applied directly to the patient's skin for monitoring purposes and, as my device only passes 9 μA or less, it is safe for continuous peroperative use, allowing the surgeon to operate uninterrupted.

The observations of Miller are interesting, although in my series on only one occasion (of the 41 when the alarm sounded) was there no apparent puncture, or wet gown sleeve touching the wound[4].

Antibiotic prophylaxis and postoperative sepsis after cholecystectomy

Sir

The article by Wells *et al.* (*Br J Surg* 1989; **76**: 374–7), concerning the relationship between bile colonization, high-risk factors and postoperative sepsis, mirrored the results of a consecutive series of 504 cholecystectomies from the Westminster Surgical Unit[1] (*Table 1*).

Wells *et al.* conclude that, despite prophylactic antibiotics, bile colonization remains the major factor associated with postoperative sepsis. This is in agreement with our results. They did not compare their study group with a control group, justifiably, in view of the current body of evidence that demonstrates the value of antibiotics in biliary surgery.

In our own analysis the most common cause of wound infection was *Staphylococcus aureus*, not biliary organisms, for those patients receiving no prophylaxis. In those patients who received antibiotic prophylaxis, the incidence of *S. aureus* wound infections was significantly reduced.

Table 1 *Bile infection and wound infection in a consecutive series of 504 cholecystectomies*

	Positive bile culture	Positive bile culture with wound infection	Same organism in bile and wound infection	Negative bile culture with wound infection	Negative bile culture with *S. aureus* wound infection
Prophylactic antibiotics ($n=379$)	79/379 (21)	12/79 (15)	8/12 (66)	14/300 (5)	9/14 (64)
No antibiotics ($n=125$)	21/125 (17)	9/21 (43)	5/9 (56)	23/104 (22)	16/23 (69)
Significance (χ^2)	—	$P<0.01$	—	$P<0.001$	—

Values in parentheses are percentages

We would suggest that it is because of, not despite, antibiotics that bile colonization is the major factor associated with postoperative sepsis. This is more in line with the study by Willis *et al.*[2] who showed that in the absence of prophylactic antibiotics (*not* in the presence of prophylaxis, as quoted by Wells) wound infections were more commonly exogenous, a finding confirmed by Van Leeuwen[3].

It is because of this that we would agree with Wells in concluding that selective administration of antibiotics is inadvisable, and would add that, in choosing a suitable antibiotic, one should be chosen that has an antistaphylococcal activity.

Recessive mutation, chromosome deletion and cancer

Sir

The review by J. Berne and colleagues on recessive mutation and chromosome deletions leading to cancer (*Br J Surg* 1989; **76**: 327–30) introduces the important topic of specific DNA changes in cancer. Since the application of powerful molecular techniques to clinical material is a rapidly progressing field, recent advances in the study of breast and colon tumours merit a further note. As the authors mention, loss of heterozygosity for genes on the short arm of chromosome 11 in breast cancer and the long arm of chromosome 5 in colon cancer is well documented. However, more recent work indicates that chromosome 17 may be of prime importance in both cancers. Loss of DNA (allelic loss) from part of the short arm of chromosome 17 (17p) was identified in over 60 per cent of breast cancers studied[1,2]. Studies by the authors extending the initial series[1] suggest that allelic loss of 17p may occur in over 70 per cent of breast tumours. It has been proposed[2] that partial loss of 17p is associated with both genetically high risk forms (bilateral or familial) and sporadic breast cancer.

Eighty per cent of colon neoplasms have partial deletions of 17p (Reference 3), with particular loss of genetic material from that region of 17p containing the transformation-associated p53 gene[4]. It therefore appears that in breast and colon cancer there is a common region of deletion of the short arm of chromosome 17. This may result in loss of tumour suppressor function of the p53 gene and act as a crucial step[5] in the carcinogenic pathway.

Radioisotope imaging in the evaluation of vascular grafts

Sir

We read with interest the article '^{111}In-labelled leucocyte imaging in vascular graft infection' by Berridge *et al*. (*Br J Surg* 1989; **76**: 41–4).

We have recently used radioisotope imaging in the evaluation of vascular graft infection, and would confirm the value of these techniques. Berridge *et al*. suggested that the use of technetium-99m might confer benefits compared with the other available radioisotopes, and we would support this suggestion by reference to a recent case.

A 68-year-old woman had undergone an aortobifemoral graft in another centre in 1982. In July 1988 she presented with an inflamed false aneurysm at her left groin anastomosis. This was successfully repaired. *Staphylococcus aureus* was grown from the small length of excised Dacron® (E.I. du Pont de Nemours and Company, Edinburgh, UK) graft. This was treated with flucloxacillin.

Subsequently, a small sinus developed in the left iliac fossa incision which failed to heal in spite of further antibiotics. In January 1989 she presented with a red hot swelling in the right groin. A sinogram on the left did not demonstrate connection with the graft.

To determine whether the graft was infected, a technetium-99m hexametazime (HMPAO)-labelled leucocyte (CERETEC, Amersham International plc, Amersham, UK) scan was performed. This identified increased uptake along the whole length of the limbs of the graft. The vertical part of the graft did not seem to show increased uptake (*Figure 1*). A gallium scan for comparison (*Figure 2*) only showed uptake in the right groin.

At subsequent removal of the graft, pus was found along the limbs of the graft but not involving the vertical portion of the graft.

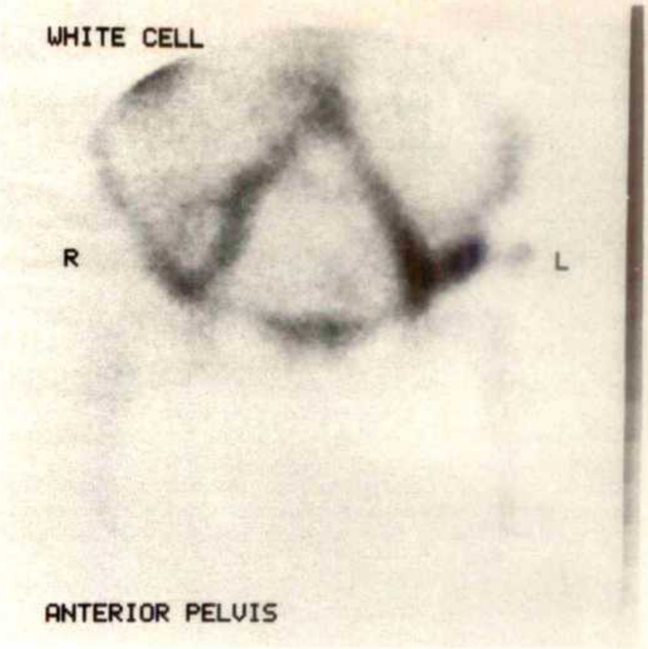

Figure 1 *Technetium-99 m scan of aortobifemoral graft*

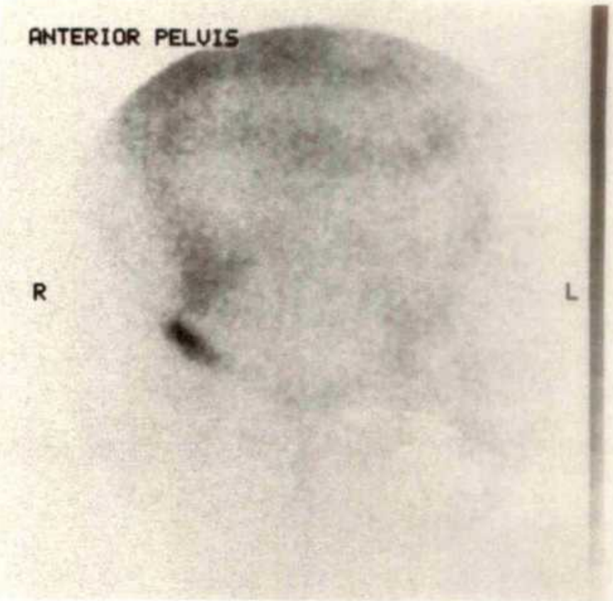

Figure 2 *Gallium scan of aortobifemoral graft*

Berridge *et al*. found no evidence of diffuse uptake in their aortic grafts and suggested that technetium-99m HMPAO might be particularly useful in this context, which this case would seem to illustrate.

Additional benefits of using technetium-99m HMPAO for these scans are its greater availability, a potential for making these scans less expensive, and, furthermore, allowing a diagnostic conclusion within 4 h, compared with the 48–72-h period required for other radioisotopic techniques. In view of these facts we would contend that technetium-99m HMPAO-labelled leucocyte scanning is the method of choice in the radioisotopic evaluation of vascular graft infection.

Inguinal hernia repair

Sir

In the paper by Mr Marsden (*Br J Surg* 1988; **75**: 263–6) and in the subsequent correspondence by Mr Tinckler (*Br J Surg* 1988; **75**: 499) and Mr Kirk (*Br J Surg* 1988; **75**: 499), a variety of older techniques, including excision of the spermatic cord, are advocated for primary and recurrent inguinal hernia repair. Mr Barwell (*Br J Surg* 1988; **75**: 931) recommends that a controlled trial of an older technique *versus* the Shouldice repair should be conducted; however, the correspondent admits that he is too biased by the success of the Shouldice repair to take part. In the absence of this now mandatory yardstick of scientific judgement, a somewhat arbitrary preference may prevail for the most common surgical procedure undertaken on adult males in district hospitals[1].

In 1985, we started a prospective controlled trial comparing the Bassini and Shouldice repairs. Five hundred and fourteen primary and 86 recurrent hernias were enrolled up to April 1989, when entry was terminated. The Cox multiple regression procedure[2] was applied in a multifactorial analysis of prospectively defined recurrence risk factors. Highly significant differences in cumulative recurrence rates have become apparent in primary repairs (6·0 per cent for Bassini *versus* 0·9 per cent for Shouldice) and in recurrent repairs (11·1 per cent for Bassini *versus* 2·8 per cent for Shouldice). Recurrent hernia and hernial sac diameter $\geqslant 8$ cm were statistically significant risk factors in the Bassini but not in the Shouldice group.

Outstanding results of single institutions in hernia repair have not demonstrated whether these results were due to superiority of specialization or to superiority of method; it is noteworthy that Bassini reported a recurrence rate of only 2·8 per cent 100 years ago[3]. To our knowledge, this is the first trial showing the superiority of the Shouldice method in the routine practice of a busy general surgical unit.

Whilst in 1890 Bassini[3] published a letter of recommendation by a superior military officer in support of his achievement, we adhere to the controlled trial to demonstrate that the Shouldice repair is the first scientifically tested progress since the original Bassini repair.

Book reviews

Operative Hand Surgery. 2nd ed.

D. P. Green. 210 × 260 mm. Pp. 804 + 1648 + 2442. Illustrated. 1988. Edinburgh: Churchill Livingstone. £175 00.

The second edition of this comprehensive textbook on operative hand surgery is a welcome successor to the first. The overall plan to describe several procedures, the indications for them and the personal preference of the author is ideal for all those interested in hand surgery, from residents to the very experienced. Each chapter is extensively referenced and the illustrations throughout the book are first class.

The striking feature of the book, apart from its overall excellence, is its layout which, being alphabetical, produces an unusual distribution of topics. Thus in Volume Two there are four chapters on fractures and dislocations, but also other chapters in Volume One. Similarly, there is an excellent chapter on free skin flaps in Volume Two, but a whole section devoted to skin cover in Volume Three. The section on incisions in the hand and wrist is in the midportion of the third volume. This layout is confusing to the reader but should not be allowed to detract from the overall quality. The new edition also contains eight new chapters on microsurgery, which seems excessive when compared with the space allocated to some other subjects, for example, 20 pages for infections of the hand.

It is difficult to particularize about the chapters in the book, most of which are comprehensive, authoritative and well illustrated. We found the chapters on skin preparation and use of tourniquets, amputations, carpal dislocations and instability, nerve repair and grafting, open injuries of the hand and skin flaps particularly valuable.

It would have been valuable to have seen a more critical assessment of the indications and the results for some of the procedures described, for example, vascularized joint transfers.

Overall this is the best presented, best written and best researched book on hand surgery presently available in the English language. We recommend it most strongly for all those who have an interest in hand surgery.

Hardy's Textbook of Surgery. 2nd ed.

J. D. Hardy. 203 × 280 mm. Pp. 1348. Illustrated. 1988. Philadelphia: J. B. Lippincott Company. £25 00.

This is a large, dense, compact textbook of surgery covering all aspects from basic and support considerations to general surgery in all its aspects, cardiothoracic surgery, paediatric surgery, plastic and reconstructive surgery, orthopaedic surgery, urology and neurosurgery. In addition, there is a short chapter on gynaecological surgery as it affects the general surgeon and there is a chapter dealing specifically with the hand. There are also good chapters on immunobiology and transplantation and at the end there is a practical chapter presumably aimed at the practising resident. The book is lavishly illustrated, both with line drawings and black-and-white photographs, and contains such interesting titbits as pictures of spiders of North America most likely to produce a dangerous bite.

It is lavishly referenced both in terms of up-to-date papers and a general bibliography; the index appears to be comprehensive and it is set out in double columns to the page. I am impressed with the clarity of the printing given the quality of paper used. It is certainly not a book for the British undergraduate medical student, neither is it one which I suspect a fellowship candidate would want to buy. On the other hand, it is so comprehensive that it would make an extremely good reference book when required. For example, when other texts had failed me I was able to find some information here about tumours of Zuckerkandl's organ. It would therefore be a valuable asset to any surgical library for this purpose!

Management of Abdominal Hernias

H. B. Devlin. 216 × 280 mm. Pp. 203. Illustrated. 1988 London· Butterworths. £60.00.

This book is a practical treatise on abdominal hernias of a manageable length that should satisfy both the learner and the experienced surgeon There is a tendency to think that the larger multi-author book is the ultimate achievement and that for hernias this has already been achieved by the Nyhus and Harkins book 'Hernia' Such a book may act as an encyclopaedia but it is never read from start to finish. The other type of book is by a single author, it is shorter and may be less comprehensive but its message is more easily transferred because of its singular experience and uniformity. This book on abdominal hernias delivers its one-author message in an exemplary way and is far more likely to be read from cover to cover. The fact that some parts have been previously published must be interpreted as indicating that their contents have withstood the test of time well. There is no need to excuse this new book as the author does in his Preface. The past is important and Bassini is just as important as Shouldice. Similarly, anatomy is emphasized as it should be but on equal terms with the economics of hernia repair The line drawings of Gillian Lee are to be specially recommended because they are clear, accurate and appreciated as true representations by the surgeon. The format of double columns allows for well-spaced illustrations and subheadings, and the relatively heavy paper and clear type makes this a pleasant book to hold and read Its presentation is a credit to Butterworths. As most of us start learning surgical techniques with hernia repair and proceed to earn our living repairing hernias, and since hernia repair is one of the commonest operations and a frequent cause of lost time at work, this book deserves a wide circulation to all surgeons at any stage of their career. This review copy will be left accessible to the junior staff; it belongs neither to the coffee table nor to the library shelf; it should become worn and battered with use

Progress in Vascular Surgery

J. S. Najarian, J. P. Delaney. 235 × 155 mm. Pp. 469. Illustrated 1988. Chicago. Year Book Medical Publishers Incorporated. £52.50

This book is based on lectures from a course in surgery at the University of Minnesota Medical School. Lectures often transpose poorly to the written page unless carefully edited. The book is not a review of recent progress in vascular surgery as the title suggests and more is the pity Several chapters titillate the reader with headings such as 'What's new in . . .', 'Recent improvements in . . .' but turn out to contain standard material long associated with their authors. In the chapter on popliteal and tibial bypass, for instance, no mention is made of the Miller cuff, the Taylor patch, arteriovenous fistula or the use of deep leg veins, all recent techniques currently undergoing evaluation Similarly, the skew flap technique is omitted from the chapter on amputation The views on carotid surgery indications might give some neurologists an apoplexy. Nevertheless, amongst all this material are some nicely written pieces on such difficult subjects as Raynaud's phenomenon. Panel discussions at the end of each section are published verbatim. This is tedious for the reader because to gain useful information one has to sift through phrases such as 'let us have a hand of applause for the panel' (surgeons always have been self-congratulatory) and even 'Nancy, give him some heat'. To include a discussion among panellists on the suicide of a colleague seems in poor taste at the very least The English in the panel discussions is even worse than that in the written chapters. Sentences stretching over seven lines and containing such words as 'knowledgeably' require the blue pencil. The editors seem to have done little more than arrange the chapters in order

While containing much useful information this book cannot be recommended; the cost is high at £52.50 but one can fairly say that the language, if not the book, is priceless.

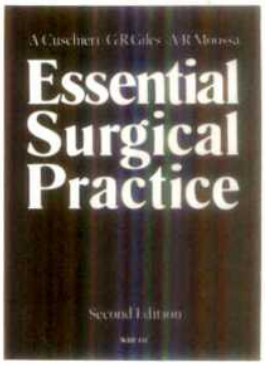
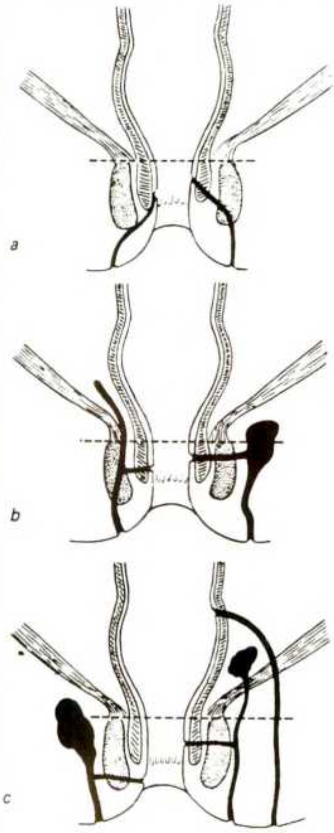
Essential Surgical Practice Second Edition

Edited by
A Cuschieri MD ChM FRCS(Eng) FRCS(Edin)
Professor and Head of Department of Surgery, University of Dundee, Ninewells Hospital, Dundee, UK
G R Giles MD FRCS
Professor and Head of Department of Surgery, St James's University Hospital, Leeds, UK
A R Moossa MD FRCS(Eng) FRCS(Edin) FACS
Professor of Surgery and Chairman of the Department of Surgery, University of California, San Diego; Surgeon-in-chief, University of California Medical Center, San Diego, California, USA





★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

Reviews

'What differentiates this textbook of surgery from many others is the clarity and simplicity of the text, the very liberal use of complementary tables, the illuminating simple diagrams, and the book's clinical relevance. The ease with which it may be read and the subject material understood makes this book a superior choice for students and residents interested in learning the essentials of surgical practice.'
The New England Journal of Medicine

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'. . . Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'
New Zealand Medical Journal

Concise Contents: General surgical aspects • Trauma • Head and neck surgery • Neurosurgery • Thoracic surgery • Cardiac surgery • Vascular surgery • General surgery • Genito-urinary surgery

1988 1456 pages 272 x 202mm Hardcover Illustrated – 604 line and 891 halftones

HICON

A major innovation in multiple ligation.

LIGACLIP*20/20
Multiple Clip Applier
and Reloading Unit.

The LIGACLIP 20/20 offers you the following benefits:

CONTROL	*Accurate positioning of the clip on the vessel is possible without applying pressure to instrument handles.*
SECURITY	*The closure mechanism enhances clip security in the applier jaws during closure.*
SPEED	*Automatic clip advance dispenses with need for removal of the instrument from the ligation site.*
VISIBILITY	*Angled jaws provide excellent visibility and control over staple placement.*
ECONOMY	*The instrument can be reloaded with 20 medium tantalum clips.*

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting Authors are advised to consult the *British Medical Journal* 1988, **296**: 401–5 or the *Annals of Internal Medicine* 1988, **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p)

Typescripts

Papers should be typewritten on A4 paper (210 x 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page. title page, summary, text, acknowledgements, references, tables, legends for illustrations

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications, (3) the department and institution to which the work should be attributed, (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed, (5) sources of financial support, (6) keywords

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s), the top of the illustration should be indicated Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension Abbreviations should be used consistently throughout the text but must be clearly defined

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**. 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s), title of paper, journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number, page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis *Ann R Coll Surg Engl* 1984; 66: 184–6 The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example·. Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag 1981: 123–63.

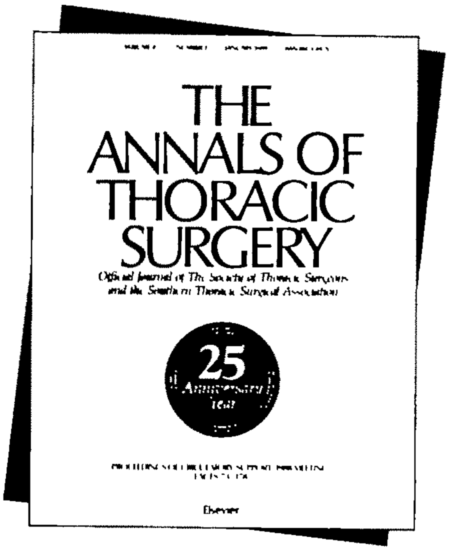
The Annals of Thoracic Surgery



Official Journal of The Society of Thoracic Surgeons and the Southern Thoracic Surgical Association

Editor: **Thomas B. Ferguson, M.D.,**
Barnes Hospital, St. Louis, MO

For 25 years, **The Annals of Thoracic Surgery** has provided outstanding original coverage of recent progress in chest and cardiovascular surgery and related fields. A forum for the exchange of knowledge and ideas for all thoracic surgeons, this timely journal features case reports, "How To Do It" articles, collective reviews, book reviews, editorials, letters to the editor, and supplements for symposia.

Authoritative — As the official journal of The Society of Thoracic Surgeons and the Southern Thoracic Surgical Association, **The Annals** enjoys outstanding editorial leadership and maintains rigorous selection standards.

Clinically Oriented — If you're the kind of professional who's always looking for improved techniques that will make life easier for your patients (and yourself), **The Annals of Thoracic Surgery** is ideally suited to help you.

Comprehensive — As a subscriber, you'll enjoy not only timely articles dealing with conditions of the heart, lungs, esophagus, and great vessels, but also research papers on a wide variety of related thoracic and cardiovascular topics.

NEW FROM BUTTERWORTHS

MANAGEMENT OF ABDOMINAL HERNIAS

H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Management of Abdominal Hernias is the most comprehensive work to date on the subject In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies

★ **the author is a leading authority on hernia management**
★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief "

British Journal of Surgical Practice

"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it

"This is a very readable and enjoyable book It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it "

British Journal of Hospital Medicine

Concise contents: Preface · General introduction and history of hernia surgery · Essential anatomy of the abdominal wall · Epidemiology and aetiology of primary hernias in adults · Logistics and economics of hernia repair · Principles in hernia surgery · Anaesthesia · Complications of hernia in general · Groin hernias in babies and children · Umbilical hernia operation in babies and children · Diagnosis of a lump in the groin in the adult · Inguinal hernia in adults · Femoral hernia · Extraperitoneal or preperitoneal repair of groin hernias using prosthetic reinforcement · Umbilical hernia in adults · Epigastric hernia · Obturator hernia, lumbar hernia, sciatic hernia, supravesical hernia · Spigelian hernia · Incisional hernia (excluding parastomal hernia) · Parastomal hernia · Complications of hernia repair · Epilogue and general conclusions · Biographical notes · References and further reading · Index

March 1988 222 pages 276 x 219 mm Hardcover Illustrated – 11 half tones and 267 line drawings 0 407 00348 7 £60.00

Palliative treatment of hepatic tumours

Approximately 25 per cent of all patients with cancer have or will develop hepatic metastases and less than 20 per cent of these individuals can be considered for radical liver surgery. For the remainder other effective treatments are desirable, given the poor quality of life for most patients with liver metastases. Earlier studies of the natural history of liver metastases, carried out some 20 years ago by my group and others, showed that the median survival time in primary liver cancer was only 2 months and that in the case of metastases from pancreatic, gastric, breast and colorectal cancer it ranged from 2 to 5 months. As only the most healthy patients receive active treatment, with its risk of severe side-effects, we have suggested as a guideline that any treatment which does not quadruple the survival figures mentioned above should not be used outside the context of controlled studies. Employing this definition, most of the treatments now used should still be regarded as experimental, particularly in the case of metastases from colorectal cancer.

Chemotherapy for liver metastases

During the past 30 years, chemotherapy has been the leading method of treatment for liver metastases Despite varied administration schedules and routes (intra-arterial, intraportal, intraperitoneal), use of sophisticated apparatus such as implantable pumps, and varied mixtures of cytostatic agents, we seem to have added little to the success of this approach. It has also proved difficult to control tumour growth without affecting normal tissues and producing severe side-effects. Another important problem so far neglected is that after each treatment cycle there is rapid compensatory growth which often makes the end result the same as if no treatment had been given. It has also been observed that treatment directed towards one region may well result in compensatory growth outside the region. For example, regional therapy for hepatic tumours often appears to be associated with accelerated growth of extrahepatic tumour.

Most of the experience to date favours treatment repeated at short intervals and, if possible, throughout life. In our view, the goal should be to retard and control tumour growth by continuous therapy. Problems with systemic infusion chemotherapy, notably severe side-effects and difficulties with long-term maintenance of treatment, have stimulated study of alternative routes of administration. In a recent randomized study, regional intra-arterial chemotherapy was compared with systemic venous chemotherapy[1]. Objective signs of response were seen in 62 per cent of the first group and 17 per cent of the second group. However, there was no significant difference in actuarial survival rates at 24 months (22 and 15 per cent respectively). In addition, continuous intra-arterial 5-fluorodeoxyuridine chemotherapy was followed by significant problems including chemical hepatitis (79 per cent), biliary sclerosis (21 per cent), peptic ulcers (17 per cent) and gastritis/duodenitis (21 per cent).

Many attempts have been made to reduce the systemic toxicity of cytostatic drugs For example, Onahara *et al.*[2] used sodium thiosulphate intravenously in parallel with aggressive intra-arterial infusion of cisplatinum. They reported almost no side-effects despite the fact that the efficiency of treatment was not reduced.

Ischaemic and metabolic treatment

The Nobel prize winner, Warburg, suggested 50 years ago that metabolic manipulation could be effective in the treatment of tumours. Such manipulation could include reduction of oxygen supply and the use of glucose analogues to perturb glucose metabolism. For more than 25 years, our own group has studied ischaemia as a treatment for hepatic tumours. Initially, we considered that the liver was an ideal organ for this treatment as hepatic metastases are supplied solely by the hepatic artery, while the normal parenchyma has a dual supply from the hepatic artery and portal vein. Attempts to retard tumour growth by hepatic artery ligation, total hepatic dearterialization and intermittent hepatic artery occlusion over some months were largely unsuccessful. No improvement in survival was apparent when results were compared with the natural history, although there were encouraging exceptions. For example, extremely good results have been obtained in some patients with carcinoid

0007-1323/89/080771-03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

tumours (tumour regression, disappearance of symptoms, reduction of 5-hydroxyindole acetic acid excretion) for periods of up to 60 months. Carcinoid tumours are very vascular and may be particularly sensitive to ischaemic treatment. In addition, the compensatory growth is much slower than that observed in most other tumours[3].

It is now quite clear that tumours are very sensitive to ischaemia. Vascular occlusion for less than 1 h may induce irreversible changes, and it has become obvious that the endothelial cells within tumour vessels are most sensitive to mechanical, toxic and metabolic injury. This is in contrast to the tumour cells, which are generally rather resistant. It is well known that tumour vessels have no smooth muscle layer and have instead an extremely well developed intima. Denekamp[4] has suggested that the endothelial cells have a much higher (up to 2000 times greater) metabolic and replication rate than any other tissue in the body. It is likely that even very brief ischaemia leads to irreversible changes in the endothelium with swelling, blockage of flow and secondary effects on the tumour cells. It could well be that other methods of treatment such as cytostatic treatment and irradiation involve the same mechanisms.

It was long believed that growth of tumour cells was autonomous and that these cells were incapable of regenerative and compensatory growth. However, studies in our laboratory have shown that a replication peak occurs 24 h after a 1-h period of ischaemia. This offers interesting potential for a combination of intermittent ischaemia followed by antimetabolite treatment 20–24 h later. We have collaborated in developing an implantable device which allows repeated occlusion of the hepatic artery. We have used the device to occlude the hepatic artery twice daily for life, ischaemia being effected on an ambulatory basis by the patients themselves. Our early results offer promise[5].

We are no longer convinced that ischaemia is applicable only to tumours in organs with dual vascular supply, and have used the approach in patients with portal venous obstruction and in those with cancers of other organs. Hepatocellular carcinoma is usually resistant to almost any treatment, including total hepatic dearterialization. To our surprise, pronounced tumour shrinkage has been observed recently in two patients treated with pulsed ischaemia, both of whom had portal venous occlusion which made the repeated ischaemia total.

Embolization

Alternative techniques for ischaemic treatment involve embolization of microspheres of starch or albumin to obstruct arterial tumour flow. Redistribution of blood flow to hepatic tumours has also been attempted with drugs such as noradrenaline and/or propranolol[6]. The main problem with such methods is that they require an intra-arterial catheter, which usually prevents daily self-administered ambulatory treatment and also makes it difficult to achieve intermittent occlusion. Such drawbacks also apply to lipoidal embolization.

Despite the flood of publications on embolization, most of the results are based on anecdotal reports or uncontrolled studies. However, success has been reported in patients with such diseases as hepatocellular carcinoma and metastases from melanoma, islet cell tumours and colorectal cancer. Despite the fact that an objective response is often seen, significant prolongation of median survival has not been demonstrated.

It is also important to underline the morbidity associated with embolization. Nausea, vomiting, fever, abdominal pain, paralytic ileus and transient elevation of liver function tests are seen in almost every patient, but rarely occur after pulsed ischaemia. In addition, severe complications such as gallbladder infarction (11 per cent), acute pancreatitis (4 per cent), delayed formation of gallstones (2 per cent), hyperuricaemia (1 per cent), gastroduodenal bleeding (1 per cent) and hepatoma rupture (1 per cent) are reported [7]. Serial assessment after gel-foam embolization has shown severe liver damage, particularly in patients with underlying hepatic disease[8]. An interesting study comparing the results of repeated arterial embolization, single embolization plus monthly 5-fluorouracil, and monthly 5-fluorouracil alone in patients with unresectable hepatocellular cancer has recently been published[9]. Repeated embolization proved the most effective treatment: complete response was seen in one patient in this group and a partial response occurred in 62 per cent of patients (compared with 48 and 10 per cent in the two other groups). One can speculate that if it was possible to repeat embolization at shorter intervals treatment might be more effective.

Future treatment

It is my strong belief that attempts should be made to develop a palliative treatment for patients with liver tumours which is simple, can be performed on an ambulatory basis for life, involves active participation by the patient, and which has minimal or no side-effects. Such treatment should not reduce mental and physical activity. At present the goal should be growth control and not cure.

Aids in the diagnosis of acute appendicitis

J. Hoffmann and O. Ø. Rasmussen

Department of Surgery D, Glostrup Hospital, University of Copenhagen, DK-2600 Glostrup, Denmark

Correspondence to: Mr J. Hoffmann

Methods used to improve the accuracy of diagnosis of acute appendicitis are reviewed. Laparoscopy, barium enema, ultrasonography and computer assistance have all been shown to improve accuracy, but no one method is of proven superiority. Such diagnostic aids or intensive in-hospital observation must be used to reduce the 15–30 per cent negative laparotomy rate when acute appendicitis is suspected, without increasing the incidence of appendiceal perforation.

Keywords: Acute appendicitis, laparotomy, diagnosis

Although abdominal surgeons have been confronting acute appendicitis for more than 100 years, its diagnosis remains elusive. Some senior surgeons can diagnose acute appendicitis accurately in over 80 per cent of cases[1,2] However, in most cases, it is more junior surgeons who are responsible for deciding whether a patient with right iliac fossa pain should be operated on or not. Their decision may be wrong about 50 per cent of the time[1–5]. Accuracy rates, illustrated by the number of normal appendices removed, will also vary according to the patient population involved Among young male patients the negative appendicectomy rate is relatively low (5–22 per cent[1,6–12]), while for women of childbearing age the figure may be as high as 30–50 per cent[1,6,7,9–11,13–17]. In young children the diagnosis may be wrong in 30–46 per cent of cases[7,10,11]. The difficulty of diagnosing acute appendicitis in old age is reflected by the high incidence of perforation, 60–90 per cent in many reports[7,10,13,14,18–21], rather than by a high rate of negative appendicectomy[9,14,21,22]. Diagnosis is also difficult during pregnancy and may result in both maternal and fetal mortality[13,23–25]. In the latter groups of patients the diagnosis is difficult for doyen and novice alike. Appendicitis is a great leveller in surgery, an antidote to diagnostic complacency.

The problem arises because patients presenting with acute right iliac fossa pain may have acute appendicitis, which requires surgery, or some other cause of pain, which may not The surgeon resolves the dilemma in one of two ways: by observation until the signs and symptoms make the diagnosis more obvious or by immediate operation. As the incidence of perforation is usually proportional to the duration of the disease process, traditional teaching has encouraged surgeons to operate even when the diagnosis is probable rather than wait until it is certain. This teaching has been challenged by some[8,26–30] who have shown that intensive observation in hospital can decrease the incidence of negative appendicectomy without increasing the rate of perforation. Prolonged observation is, however, not an ideal solution as it is expensive to the health services. Furthermore, no-one can be sure how many of these patients in fact have appendicitis which resolves spontaneously under observation only to recur at a later date[29,31–33].

The morbidity and mortality rates associated with appendicitis are greatly increased when perforation ensues[7,10,11,13,14,31]: wound infection rates may treble, intra-abdominal abscess formation increases 15-fold[13] and mortality may be 50 times greater[34]. Appendiceal perforation can also cause tubal infertility[35]. It is therefore obvious that the aim of the surgeon must be to prevent perforation at any price. The price is the high rate of removal of a histologically normal appendix, which is not inexpensive as it carries with it a complication rate not much lower than that after removal of a pathological appendix[6,7,9–11,13,14,36–38]. The operation of negative appendicectomy is accompanied by the usual spectrum of immediate postoperative complications in up to 15 per cent of patients[13]. Some patients may even die after negative appendicectomy[6,10]. Additional patients may suffer late complications such as intestinal obstruction[10,16,37], incisional hernias[37] and sterility due to fimbrial adhesions[6,15,39,40]. The latter postulate has, however, been recently refuted[35]

Thus, a surgeon confronting a patient suspected of having acute appendicitis is wedged between the Scylla of perforation and the Charybdis of negative appendicectomy. He or she has, however, been taught the axiom that the number of negative appendicectomies will be inversely proportional to the number of perforations. It appears, therefore, that surgeons have created for themselves a surgical security zone which allows them to accept a 15–30 per cent negative laparotomy rate with impunity[6,14,41–43].

The aim of this review is to show that measures are available to aid in the diagnosis of acute appendicitis rendering this orthodox surgical teaching obsolete.

White blood cell counts

This diagnostic test will be reviewed not because it has great value in the diagnosis of acute appendicitis but because it is so universally used and therefore needs to be placed in perspective.

It is clear[44–47] that 80–85 per cent of patients with acute appendicitis will have a total white blood cell count of over $10\,000/\mathrm{m}^3$ Neutrophilia of >75 per cent will occur in 78 per cent of patients[44,48]. When the white cell count and neutrophil count are taken together <4 per cent of patients with acute appendicitis will have normal levels[44,46] However, the white cell count is raised in 25–70 per cent of patients with other causes of acute right iliac fossa pain[46–48]. Leucocytosis increases with the duration of the disease process[44], but even a perforated appendix may present with a normal white cell count Of note is the observation of some[47] who found that, if the white cell count is repeated after some hours, it remains high in patients with acute appendicitis but tends to fall in those without appendicitis. Others have reported that the white cell count[46] and neutrophil count[49] are especially sensitive in children. In elderly patients with appendicitis the white cell count has been variously reported as being either reliable[14,18,21,22,44,50] or unreliable[19,34,51].

Thus, although a raised white cell count is a highly sensitive test for acute appendicitis, it is rendered almost useless by its low specificity and it has little diagnostic value[6,9,13,14,36,41,47,48]. Where the white cell count is at variance with the clinical signs, the latter should take precedence[48]. The only value of the white cell count would seem to be to prompt observation rather than operation in a patient who has equivocal features of appendicitis together with a normal count[44–46].

Plain radiography of the abdomen

Although there is no radiological sign that is pathognomonic for the diagnosis of acute appendicitis, plain radiography of the abdomen has been used for this purpose since 1906[52] It is a highly inaccurate investigation and is mentioned here only to discourage its use.

The use of plain abdominal radiography is based on the demonstration of one or more of the following signs[52–61]: faecolith of the appendix, gas in the appendix, air–fluid levels or dilatation of the terminal ileum, caecum or ascending colon (i.e. signs of localized paralytic ileus), deformity, oedema or obliteration of the caecal shadow, blurring or spasm of the right psoas muscle, scoliosis of the lumbar spine, widening or obliteration of the properitoneal fat line in the right iliac fossa, haziness or disappearance of the pelvic peritoneal fat stripe, density or haziness over the right sacroiliac joint, and free intraperitoneal or retroperitoneal gas. Not one of these signs is specific for acute appendicitis and they may be found in patients with other causes of right iliac fossa pain and in many normal subjects

Any one or more of these signs have been found in 24–95 per cent of patients with appendicitis[52–60]. The sensitivity of the test increases with the degree of inflammation[52,53,56,59] and the expertise of the interpreter[57]. One study[61] found that 60 per cent of patients with positive radiographs did not have appendicitis. Another[55] found at least one of the signs in 38 per cent of 'normal' subjects. Other more recent studies have also found plain radiographs to be unreliable[9,14,22,36,62]. The incidence of positive radiographs among patients with causes of right iliac fossa pain not requiring surgery has varied between 4 and 73 per cent[52,53,59–61] It must be mentioned, however, that 1–10 per cent of the patients with false positive radiographs for appendicitis had other intra-abdominal diseases which required surgery, such as perforated ulcers or colonic diverticula, torsion of ovarian cysts and intestinal obstruction[52,53,60,61].

Furthermore, irradiation hazards, especially to two groups most frequently requiring elucidation, namely women of reproductive age and children, as well as the cost and overloading of radiology departments[58,61], make this investigation of low diagnostic yield especially unattractive.

Barium enema

A normal appendix can be filled with barium on barium enema examination while an appendix obstructed by the process of appendicitis will not allow the passage of barium. This is the premise on which the barium enema diagnosis of acute appendicitis is based However, both statements are open to question. The appendix of about 10 per cent of normal persons cannot be demonstrated on barium enema[60,63–66]. On the other hand, barium may entirely fill an inflamed appendix[59] or it may fill an appendiceal lumen without allowing the examiner to determine with certainty whether this represents the entire length of the lumen or not[67,68]. The appendix may be inflamed distal to the point reached by the barium. This latter situation of partial filling can usually, but not always, be diagnosed radiologically as the lumen will be cut off rather than tapering to a normal tip, which is described as bulbous. This cut-off is considered a highly reliable sign of appendicitis[60,64,65,69,70].

Therefore non-filling of the appendix alone is not pathognomonic of acute appendicitis and must be accompanied by signs of inflammation usually registered as deformity, spasm, displacement and/or thickening of the caecum, ascending or sigmoid colon or terminal ileum[59,60,64–66,69,71]. The examination is described as requiring no preparation and minimal pressure and manipulation of the abdomen, and is entirely free of complications including appendiceal perforation[59,60,63–66,69,71,72].

Two papers report a sensitivity and specificity of 100 per cent[69,71]. In four other studies[60,63 65] the sensitivity of barium enema ranges from 90 to 100 per cent and the specificity from 75 to 98 per cent. These results must be tempered by the fact that the examination was technically unsatisfactory or non-diagnostic in up to 16 per cent of cases, and these cases were excluded from the statistics[64,69,71]. Thus barium enema is highly accurate in the diagnosis of appendicitis although false positive examinations do occur, especially due to gynaecological diseases[60,64,73], and some discourage its use[14 22,67,68].

The great advantage of barium enema examination is that it is available in most hospitals and does not require special equipment other than that already available in most radiology departments. A further advantage is that barium enema can diagnose other diseases, which may be confused with acute appendicitis, such as colonic carcinoma, terminal ileitis and ischaemic colitis[63,70,72] Its disadvantages lie in its relatively high incidence of technical failure and its radiation hazard[14,58].

Ultrasound[34,74–85]

If the appendix can be seen on ultrasound examination this is taken to indicate the presence of acute appendicitis. If the organ cannot be seen, appendicitis is excluded. The appendix is seen as a blind-ending, immobile, non-compressible structure which cannot be displaced on pressure with the ultrasound probe. The varying echodensity of the lumen, mucosa and thickened wall of the inflamed appendix gives a characteristic ultrasound picture which has been dubbed a 'bull's eye' or 'target'. A faecolith in the lumen or fluid surrounding the organ are considered confirmatory signs of appendicitis. The examination will be non-diagnostic in 3–11 per cent of cases because of pain, guarding, obesity or overlying gas[77,80,82–84]. Among seven studies in the literature, the sensitivity ranges from 75 to 89 per cent and the specificity from 86 to 100 per cent[77,78,80–84] Less accurate results are reported in another study, but the authors claim that their equipment was not optimal[79] Poorer results are also reported for retrocaecal appendices[79], early appendicitis[85] and perforated appendices[80]. In other studies, however, the diagnosis of perforated appendicitis was found to be very accurate[82,85] Another factor detracting from some of the studies is the fact that some of the patients diagnosed ultrasonically as having appendicitis were not operated on[80,83,84]. The authors believe that these were mild cases which resolved spontaneously. One might argue that these patients should be regarded as false positives.

Besides being highly specific in diagnosing appendicitis in the hands of experts, ultrasound has further advantages. It is accurate in excluding diseases that do not require surgery (such as mesenteric adenitis, terminal ileitis, ureteric stones and especially gynaecological disorders) as well as diagnosing diseases other than appendicitis which do need operation (such as ectopic pregnancy[79,80,84]). Ultrasound is non-invasive and can be used in pregnancy[82]. Its main disadvantage lies in the fact that it requires special equipment and special expertise The latter may not be available 24 h per day[34,84]. Further disadvantages are its relatively low sensitivity in some studies and the fact that it is difficult to use in obese or distended patients[82–84].

Laparoscopy

Laparoscopy has the attraction of being the only investigation that can view the appendix directly The criteria used for the diagnosis of acute appendicitis are the identification of an inflamed appendix or the presence of signs of inflammation in the right iliac fossa when no other pathology can be found to account for this. Appendicitis is excluded if a normal appendix is seen or if another cause of intra-abdominal pathology is revealed to explain the clinical picture[15,16,39,40,86–89].

Previous laparotomies, obesity and abdominal distension are generally considered contraindications to laparoscopy[90–92]. In addition to patients in whom laparoscopy is contraindicated, a further 14 per cent of patients cannot be examined because of technical difficulties[40,93] Furthermore, the appendix cannot be directly visualized in 7–83 per cent of patients (usually about 15 per cent), but indirect signs may nevertheless point toward appendicitis[15,16,39,40,87,89,93].

Two papers report an accuracy of 100 per cent[86,88]. In six other studies the sensitivity varies from 70 to 100 per cent and the specificity from 73 to 95 per cent[15,16,39,40,87,93]. Jersky *et al* [39], however, point out various pitfalls: an appendix thought macroscopically to be inflamed at laparoscopy may nevertheless be normal. The appendix and Fallopian tube may be inflamed simultaneously. The appendix is often not seen throughout its length. Even if another convincing explanation for the clinical signs is revealed the patient may yet have appendicitis. Nevertheless, negative laparotomy can be obviated in as many as one quarter to one half of the patients by using laparoscopy[15,40,86,88–90,93]. In one study, the negative laparotomy rate was reduced to 1 per cent[87]. This occurs mainly because laparoscopy can accurately diagnose gynaecological conditions An additional advantage of laparoscopy is that it can diagnose other causes of an acute abdomen requiring surgery, such as perforated peptic ulcer. It can be used during pregnancy[15]

The major disadvantage of laparoscopy is its invasiveness. It requires a general anaesthetic (although some[88] perform laparoscopy under local anaesthetic) and is in fact an 'operation' that may result in many of the complications of any abdominal procedure. These complications are infrequent and usually minor, in the form of wound problems, but deaths[86] and life-threatening complications such as perforation of major blood vessels[93] have been reported. The incidence of these complications is, however, lower than after negative appendicectomy. Another disadvantage is that laparoscopy requires special equipment and expertise.

Computers

Structured data gleaned from history-taking and physical examination may be fed into a previously programmed computer, which can then make a diagnosis of acute appendicitis or non-specific abdominal pain. Such systems[94] have been used since 1972 in tens of thousands of patients in many centres, although predominantly in the UK It has been shown, using a computer, that the accuracy of distinguishing between acute appendicitis and causes of abdominal pain not requiring surgery increases to between 72 and 92 per cent compared with an accuracy of unaided clinical diagnosis of between 52 and 80 per cent[2–4,17,95–97]. Negative laparotomy rates drop from 18–37 to 6–10 per cent[2–4,17,95,96]. The incidence of appendiceal perforation drops from 22–36 to 4–12 per cent[2,4,95]. The mortality associated with appendicitis drops by up to 50 per cent[4,95]. Enormous financial savings accrue owing to lowered rates of complications and negative laparotomies, the number of bed-days required for observation of the patients and the decreased use of other ancillary investigations[3,4 95,96] These savings outweigh the cost of installing and running the computer[95]. A single study, however, has found that computer diagnosis was no more accurate than unaided clinical diagnosis[37]

Enthusiasm for computers has been tempered by various misgivings Some claim that it is difficult for untrained personnel to use a computer. It has been shown, however, that it is easy to use the system although it takes 2–3 months to glean the full benefit[98] Others are of the opinion that the computer is needed, but that the improvement in clinical diagnosis results not because of the computer, but because of improved clinical data gathering by the clinician[99] This is true to a certain extent, but it has been shown that clinical performance will again decrease if the surgeon is denied feedback from the computer[98] It has also been suggested that the database from one centre cannot be successfully transferred to another geographical area[98] This has been confirmed by some[37,100] but disproved by others[17,101]. In addition, clinicians may be reluctant to use computers in that they dehumanize or impinge upon the art of clinical diagnosis; but computers in fact stimulate the clinician to function more accurately and to gather clinical data more efficiently[2,4,17,95,96,101]. Finally, a point not emphasized in most of the reports is that in order to gather data for the computer one requires a conscious, communicative and co-operative patient[102] It is not possible to determine from most of the studies how many patients could not be 'computerized' because they were too young, too senile or otherwise unable to give a good history or respond adequately to clinical examination. Such patients constitute a group in which the diagnosis of the acute abdomen is most difficult[103,104]. This, however, does not occur frequently in the two studies that address the problem[2,94].

The attraction of computer diagnosis lies in the fact that it is eminently non-invasive and highly accurate. Its disadvantage is that it requires special equipment and training.

Miscellaneous

Included here are various other methods that have been used to diagnose acute appendicitis. As they have not been widely tested, their places in the armamentarium cannot yet be established.

Scoring systems

The patient's signs, symptoms and white cell count are given various scores. A patient who scores above a certain figure is considered to have appendicitis. The number of signs and symptoms included in the scoring system varies from 7 to 19 in four studies[38,62,100,102] One prospective study reports a sensitivity of 90 per cent and a specificity of 91 per cent for their system[100]. Negative appendicectomy rates could be reduced by about 30 per cent in three studies[38,62,100].

Computed tomographic (CT) scanning

CT scanning can diagnose acute appendicitis[105–108]. It is accurate for advanced cases but inaccurate in early appendicitis[105] Such a highly sophisticated and expensive apparatus can hardly be expected to be used in the day-to-day diagnosis of appendicitis, but may be of use in an occasional patient where diagnosis is very difficult[105,106]

Radioactive isotope imaging

A patient's leucocytes may be incubated with a radioactive isotope. After reinjection these leucocytes can be detected in an inflamed appendix on scanning. Technetium-99m[12,109] and indium-111[110] have been used. These three studies revealed a sensitivity of 83–89 per cent and a specificity of 92–100 per cent. In one study[109], however, the method was shown to be unreliable in diagnosing appendicitis in women, so it may need to be supplemented with an ultrasound scan to exclude gynaecological disease[12].

Diagnostic peritoneal aspiration or lavage[104,111–116]

A fine-bore catheter may be introduced into the peritoneal cavity and fluid aspirated with or without lavage in order to detect pus or an abnormal number of leucocytes as a reflection of acute appendicitis. Unfortunately, two of the commonest conditions likely to be confused with acute appendicitis, namely gynaecological infections and mesenteric adenitis, may cause a leucocyte-rich exudate in the peritoneum. Gynaecological infections may also reveal pus on lavage. A negative lavage, however, usually excludes all three conditions. The presence of pus on lavage in a young male patient would exclude mesenteric adenitis. The presence of pus or a leucocyte-rich fluid in an elderly patient with right iliac fossa signs would suggest appendicitis, as both gynaecological infection and mesenteric adenitis are unlikely

Barium swallow

A single study[117] reports a 95 per cent accuracy in the diagnosis of acute appendicitis in children using this method. Filling of the appendix with barium excluded appendicitis. Non-filling plus a 'mass effect' on the caecum was highly suggestive of appendicitis.

Conclusions

Despite the panoply of sophisticated investigations reviewed above, there is no panacea for the diagnostic dilemma of acute appendicitis. No one test can reduce the rate of negative appendicectomy to zero. It should, however, be obvious that the usually accepted figure for negative appendicectomy of 15–30 per cent, based on unaided clinical diagnosis, is no longer acceptable. This figure can and must be reduced by ancillary measures.

Which one of the 11 different investigations should one choose and which can be rejected? A final answer cannot yet be given as there are no controlled clinical trials comparing them, but some conclusions can be drawn from the data at hand.

Plain radiography of the abdomen and the white cell count are highly inaccurate and should be discarded CT scanning is expensive, and inaccurate in the early case, and cannot be recommended for routine use. Diagnostic peritoneal lavage is attractive in its simplicity but has not been shown to be of value in the average case. Radioisotope scanning and barium swallow show promise but have not yet been adequately evaluated in large numbers of patients. Both are tainted by employing radiation. Scoring systems would appear to be ideal as they are accurate, non-invasive and require no special equipment, but further large-scale trials must be awaited. Laparoscopy is effective in reducing negative appendicectomy rates but its invasiveness makes one wary of promoting its widespread use. Barium enema is accurate and is readily available in most hospitals, but is vitiated by its radiation hazard Ultrasound examination is highly attractive but has a low sensitivity in some reports. Computer evaluation is marred only by requiring expensive equipment.

Thus four investigations remain whose value has been proved in clinical practice, namely laparoscopy, barium enema, ultrasonography and the use of computers. None has been proved to be better than any other of the remaining three, but each is indisputably better than no investigation at all. Which of the four is chosen depends in the first instance on what is available in the individual hospital. If there is a choice of which system to introduce into a department, a computer or ultrasound equipment is recommended. If none of the investigations are available, intensive in-hospital observation should be employed[8,26–30].

By using diagnostic aids for acute appendicitis, prolonged observation, negative laparotomies and the incidence of perforation can be reduced dramatically, resulting in decreased financial cost, which outweighs the cost of the systems employed.

A question arises concerning which patients should be investigated and which assessed purely clinically. The vast majority of the studies reviewed investigated only those patients where doubt existed about the diagnosis. A few, especially the computer studies, investigated all patients even when the decision to operate or not to operate was 'certain'. Some studies[80,90,104] have shown that even when the diagnosis of the acute abdomen is certain mistakes are still made, suggesting that all patients should be studied. Some authors[12,80] have recommended a combination of two or more investigations to increase accuracy even more.

In 1989, the 30 per cent safety margin surgeons allow themselves in the form of negative laparotomy in patients suspected of having acute appendicitis is no longer acceptable and has to be impugned. In the age of the silicone chip and the ultrasound wave, the X-ray beam and the endoscope, laparotomy can no more be used as a diagnostic procedure for appendicitis. The Gordian knot of appendicitis' diagnosis must not be untied with the scalpel.

Endoscopic balloon dilatation of colonic anastomotic strictures

N. O. Aston, W. J. Owen and J. D. Irving*

*Departments of Surgery and *Radiology, Lewisham Hospital, London SE13 6LH, UK*

Correspondence to: Mr N. O. Aston, Department of Surgery, Guy's Hospital, London SE1 9RT, UK

Nine postoperative colonic and rectal strictures were treated using dilatation balloons passed over a guide-wire introduced endoscopically. Six strictures resolved after a single dilatation. The method is simple, safe, effective and avoids further surgery.

Keywords: Balloon dilatation, anastomotic stricture, rectum, colon

Colonic anastomotic strictures are usually secondary to ischaemia or leakage[1,2] (*Figure 1*). Following resections for carcinoma, some strictures will be due to recurrent disease[3]. The circular stapler may be responsible for an increase in the incidence of strictures compared with hand sewn anastomoses[4]. Most rectal and colonic strictures respond to simple dilatation but a few will be inaccessible and others fail to improve despite repeated dilatation. A further resection is technically demanding and may not be possible or advisable in all patients. We report a simple and effective method of stricture dilatation that avoids further surgery.

Patients and methods

From November 1983 to February 1987, nine patients with colonic anastomotic strictures shown on barium enema were referred for balloon dilatation (*Table 1*). Seven patients had symptoms of subacute large bowel obstruction while two were treated on the findings of a distal loop barium enema before closure of a defunctioning colostomy (*Figure 2*). All anastomoses had been hand sewn except for one reversal of Hartmann's procedure with a 31-mm EEA® stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK) which had resulted in a stricture with a 3-mm lumen 5 months later.

Technique

After standard preadmission bowel preparation and sedation with 10–20 mg of intravenous Diazemuls® (KabiVitrum Ltd., Uxbridge, UK) plus 25–50 mg pethidine a flexible sigmoidoscope or colonoscope was passed to assess the stricture. Biopsies were taken if the original resection was for a carcinoma. A 0·038 inch (0·965 mm) guide-wire was passed, via the biopsy channel, through the stricture. The endoscope was then removed and a 20 mm (diameter) × 8 cm dilatation balloon (Medi-tech, Watertown, Massachusetts, USA) was passed over the guide-wire. The balloon was filled with dilute contrast and slowly dilated to 2 atm (202·6 kPa) using a pressure gauge under fluoroscopic control until the waisting at the stricture was abolished (*Figures 3* and *4*). Pressure was then maintained for 2 min.

After dilatation the anastomosis was inspected with the colonoscope. Most of the procedures were performed as day cases. Because of the small risk of colonic rupture the dilatation was performed in the morning and the patient was examined in the late afternoon to ensure that no complication had occurred. All patients were instructed to return immediately if they experienced any abdominal pain. One month later colonoscopy was repeated and a further dilatation performed if necessary.

Results

Six patients required only a single dilatation. Two patients required a second dilatation. One patient with terminal metastatic colonic cancer died 2 days after a third dilatation for palliation of pain from obstruction.

Follow-up of the eight surviving patients has been from 12 to 54 months (median 24 months) without recurrence of symptoms.

Discussion

A minor degree of anastomotic narrowing is common. The definition of a stenosis is variable in all series[4]. With bowel in continuity any stenosis that produces symptoms is a stricture

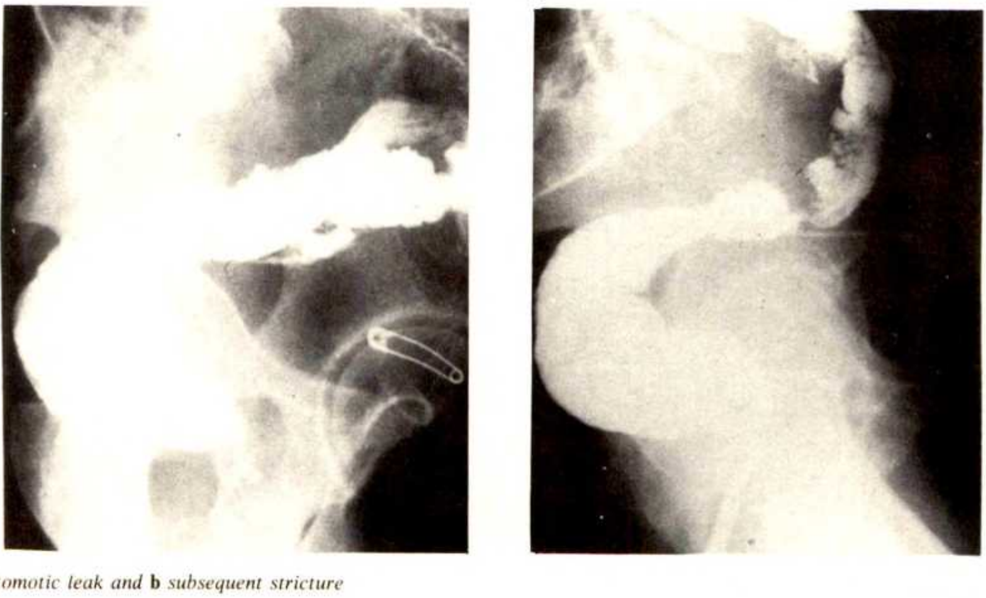

Figure 1 **a** *Anastomotic leak and* **b** *subsequent stricture*

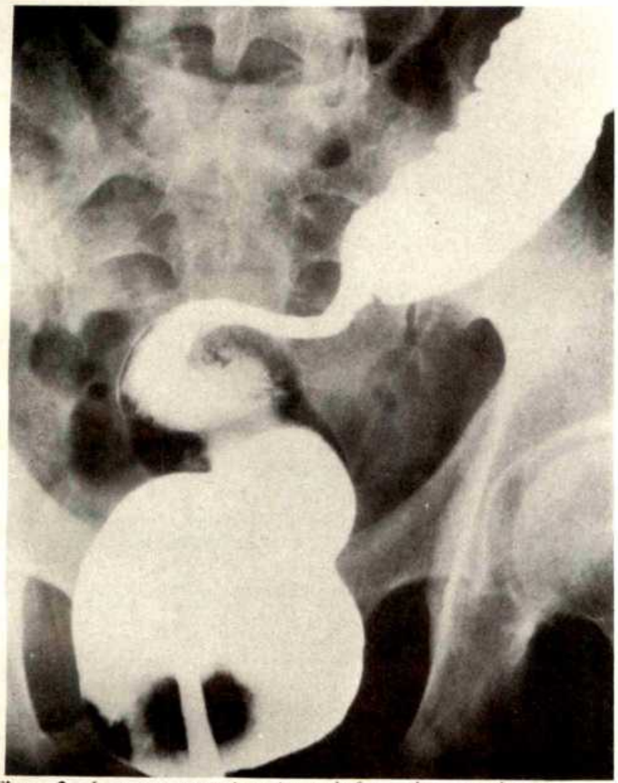

Figure 2 *Long anastomotic stricture before colostomy closure*

whatever the absolute diameter. In this series seven of nine patients had symptoms of large bowel obstruction. When a distal loop enema shows a stenosis the definition is more difficult as most will dilate spontaneously after colostomy closure. Probably only those that are very tight (less than 0·5 cm in diameter) should be dilated before colostomy closure, as with the other two patients in this study. All others should be reviewed regularly to check for the development of obstructive symptoms.

Many anastomotic stenoses will resolve over 6–12 months but a minority will cause persistent obstructive symptoms. In stapled colorectal anastomoses which developed strictures, transabdominal repair was required in 4·4 per cent[6]. Many methods of dilatation have been used. Digital dilatation may be suitable for some low rectal strictures. Sigmoidoscopes[7], Hegar dilators, Maloney's dilators[8] and stricturescopes[9] have been used. So have Eder–Puestow dilators[10] and Foley catheter balloons[11]. Gruntzig balloon catheters have been used in infants for dilatation of colonic strictures secondary to necrotizing enterocolitis[12]. Colonoscopy can be used to pass guidewires for Gruntzig-type balloon dilatation or the passage of Savary or Celestin dilators[13]. Recently transluminal partial excision of rectal strictures has been described, using a circular stapling gun after initial Hegar dilatation. The open gun is passed through the stricture and closed to excise a crescentic segment[14]. This has the potential risk of excising extrarectal tissue such as adherent small bowel or bladder and causing a fistula.

There is a single report of dilatation, using a guide-wire and a balloon, of an anastomotic stricture which may have been caused by postoperative radiotherapy[15]. Colonic Crohn's strictures have been successfully dilated endoscopically. One patient developed septicaemia soon after the dilation[16], so it may be advisable to use a single dose of prophylactic antibiotic for all balloon dilatations. For recurrent Crohn's disease at colonic anastomoses, and after anterior resection strictures that fail to respond to balloon dilatation, an endoscopic sphincterotomy has been used successfully[17].

Traditional push-type dilators (Maloney, Eder–Puestow, Savary) exert an axial shear force as well as a radial force. However, the operator does have a subjective sensation of the force required and of the tissue response. The theoretical advantage of balloon dilatation is that it only exerts a radial force and the maximal force is directed into the strictured segment. The fixed diameter of the balloon also ensures control over the extent of dilatation. The polymer material of the balloon is of low compliance and will rupture if expanded beyond its defined diameter[18,19]. As there is no tactile assessment of the completeness of dilatation the balloon must be filled with dilute contrast and viewed fluoroscopically. Dilatation should be slow to be safe.

If the stricture is very tight serial dilatation can be planned using a small balloon for the first dilatation and repeating the procedure with a larger one 1 month later.

Gruntzig-type balloon dilatation has been used successfully in the oesophagus, mainly for benign strictures[20,21] and achalasia[22]. There is little information on the benefits of balloon dilatation of malignant oesophageal strictures. The impression is that improvement is short-lived[21]. In our series one patient had skin metastases from his colonic carcinoma at the time of colostomy closure. The stricture had been secondary to an anastomotic leak (*Figure 1*). Biopsies of the anastomosis at colonoscopy did not show mucosal recurrence yet dilatation produced improvement which only lasted a few days. He died after a third dilatation that caused a pneumoperitoneum.

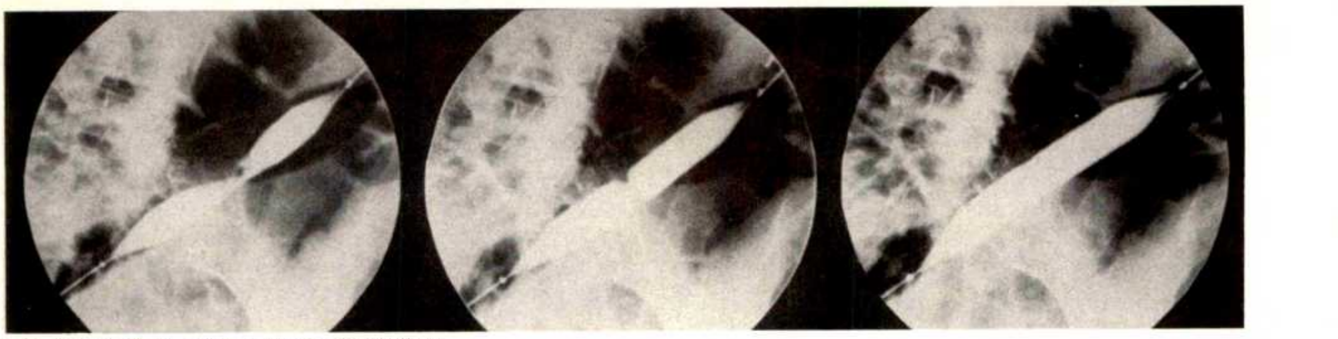

Figure 3 *Stages of dilatation; contrast filled balloon*

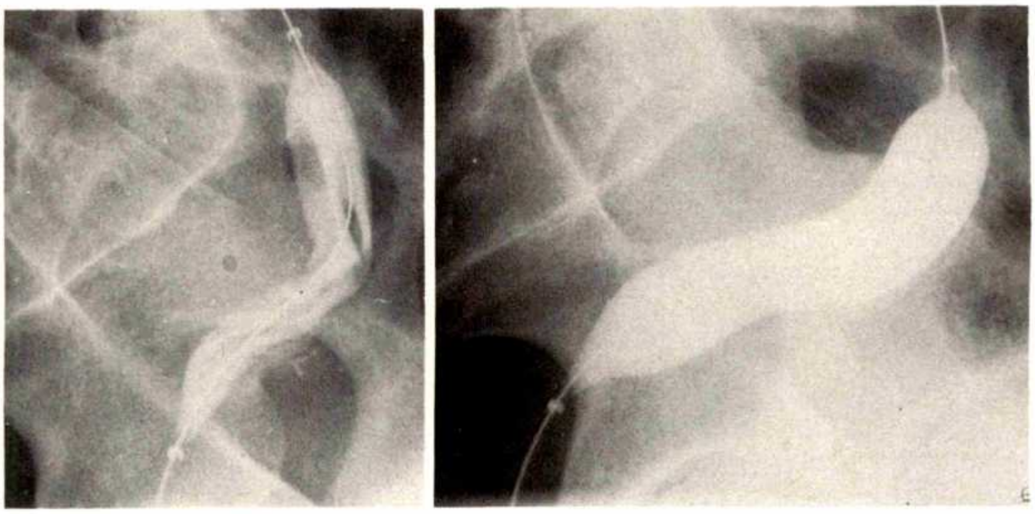

Figure 4 *Stages of dilatation of stricture in* Figure 1

Permission for a post mortem was refused but it is probable that recurrent tumour was present around the anastomosis. We would not recommend balloon dilatation for colonic strictures due to recurrent malignancy. Laser treatment is probably more effective if the recurrence is inoperable[23,24]. Neither would we recommend more than two dilatations of benign strictures if symptomatic improvement is not achieved or is transient. There should be 3 weeks or more between each dilatation provided that symptoms remain acceptable.

As endoscopic balloon dilatation is simple, successful and well tolerated it should be considered as the first treatment of symptomatic, benign, colonic anastomotic strictures.

Minor difficulties with continence may occur after low anterior resection. Intraoperative injury to the internal anal sphincter or its nerve supply may contribute to this. To study the effect of low anterior resection on the anal sphincter mechanism, anal manometry was performed on 20 patients before and 10 days after resection. Fifteen patients were studied again 6 months after operation. Resting, maximum squeeze and squeeze increment pressures were recorded. Intraoperative manometry ($n = 11$) *and presacral nerve stimulation* ($n = 6$) *were performed to determine whether peroperative injury to the internal anal sphincter had occurred. Resting and maximum squeeze anal canal pressures were reduced by low anterior resection, and did not recover. The squeeze pressure increment did not change. Division of the inferior mesenteric artery, full mobilization of the rectum and mesorectum, and rectal transection did not affect resting anal pressure, which was reduced after EEA® anastomosis* (*mean* (*s.e.m.*) *before, 40(5) mmHg; after, 27(4) mmHg;* $P < 0{\cdot}05$, $n = 5$). *Presacral nerve stimulation produced relaxation of the internal sphincter. Anal sphincter pressures are reduced after low anterior resection. The external anal sphincter and the nerve supply to the internal anal sphincter appear intact. A direct injury to the internal sphincter is postulated.*

Keywords: Rectal cancer, anterior resection, internal anal sphincter, external anal sphincter, continence

The rationale for sphincter-saving resection in patients with low rectal cancer is now widely accepted[1] and there has been a marked decline in the number of abdominoperineal resections performed[2,3].

Technical innovation, principally the introduction of circular stapling devices[4], has helped to overcome the difficulties of hand-sewn extraperitoneal colorectal anastomosis. With careful technique, a stapled extraperitoneal colorectal anastomosis appears to be as safe as a hand-sewn equivalent[5–7]. Thus the possibility of sphincter-saving resection is limited only by the need for adequate resection margins. Previously, a distal tumour-free clearance of at least 5 cm was widely recommended to minimize local recurrence. It is now clear that distal intramural and lymphatic spread is rare in rectal cancer, and a distal resection margin of 1·5–2·0 cm appears adequate in all but poorly differentiated and anaplastic tumours[1,8,9]. With this proviso, the long-term survival rates are similar for abdominoperineal resection and sphincter-saving resection[7,10].

While much attention has been paid to the cancer clearance aspects of sphincter-saving resection, the effect on the physiology of faecal continence has been less studied. The quality of life after rectal cancer excision is better in patients with sphincter preservation. However, 25–40 per cent of patients after sphincter-saving resection experience some difficulties with continence, particularly frequency and nocturnal leakage[11,12]. In the majority, stool frequency improves with time, associated with an increase in 'neorectal' capacity[13–18]. A similar phenomenon has been observed following ileal pouch–anal anastomosis for chronic ulcerative colitis[19]. While stool frequency after anastomosis appears to be a function of neorectal capacity and motility[20], impaired continence is probably related to anal sphincter injury[21].

Resting anal sphincter pressure is less in patients after sphincter-saving resection than in age-matched controls[13,22]. This observation could be explained by intraoperative injury to the sphincters or their nerve supply. This study was designed to investigate the effect of sphincter-saving resection on the anal sphincter mechanism and to determine whether intraoperative injury to the anal sphincter or its nerve supply could be detected

Patients and methods

Preoperative measurements

Twenty patients undergoing anterior resection were studied There were 11 men and 9 women of mean(s.e.m) age 64(3) years (range 34–79 years). Median tumour distance from the anal verge, measured at sigmoidoscopy, was 7 5 cm (range 5–12 cm). All anastomoses were extraperitoneal. Patients were admitted 2 days before operation and commenced on a standard bowel preparation. Preoperative anal manometry was performed on the day before operation, using a catheter, 5 mm in external diameter, perfused with saline at a rate of 0·5 ml/min and connected to a pressure transducer and a pen recorder Resting anal sphincter pressure was measured using a 1-cm station pull-through technique[23] and the maximum resting pressure was recorded. Patients were then requested to exert a maximum squeeze effort and the maximum squeeze pressure and the increment in pressure occurring with the squeeze effort was recorded at the same point in the anal canal. The rectoanal inhibitory reflex was tested by inflation of an intrarectal balloon with 50 ml of air while recording the resting anal canal pressure. A reproducible drop of 20 per cent of resting pressure was defined as a positive reflex. Patients were asked whether a sensation of rectal fullness was experienced during balloon inflation.

Intraoperative measurements

Of the 20 patients, 11 were included in the intraoperative study, seven men and four women of mean(s e m.) age 67(2) years. In addition to the measurements performed in the entire group of 20, this subgroup of 11 patients had additional measurements performed using different methodology. On the morning of the operation, benzodiazepine premedication was administered and both α-adrenergic and β-adrenergic blocking drugs were avoided In the anaesthetic room, before anaesthesia, a water-filled balloon constructed from the cuff of a modified Portex endotracheal tube[24], size 6·5, connected to a pressure transducer and pen recorder, was positioned in the midpoint of the anal canal and resting pressure was recorded. The manometry probe was held in position during the operation by suture to the perianal skin.

0007–1323/89/080783–04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

A non-perfused, stationary balloon probe was chosen for intraoperative studies because of the ease of maintaining position and the difficulties associated with a perfused probe throughout a long operation. Furthermore, the diameter of a manometry probe is not critical to measurement of anal canal pressure[25] if the probe is left *in situ* for more than 15 min.

Anal canal pressure was measured before and after induction of anaesthesia and after division of the inferior mesenteric artery in all 11 patients Pressure was recorded in ten patients after full rectal mobilization and complete excision of the mesorectum[26], as is our standard practice, and in nine patients after rectal transection below the tumour. In five of these patients, anal resting pressure was recorded after completion of colorectal anastomosis using the 31-mm diameter EEA® stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK) Any anal dilatation required to insert the instrument was achieved using the lubricated convex end of the instrument only The mean(s.e.m.) level of the anastomosis in these five patients was 4(2) cm.

Intraoperative presacral nerve stimulation

The presacral nerves are always identified and carefully preserved during mobilization of the rectum anterior to the fascia of Waldeyer as part of our standard procedure In six patients, while resting anal canal pressure was continuously measured, intraoperative presacral nerve stimulation was performed for 1 min using a bipolar nerve stimulator (Medelec MS 91, Woking, Surrey, UK) delivering square wave stimuli (duration 0·5 ms, frequency 20 pulses/min; amplitude 50 V)[27]. In four patients, presacral nerve stimulation was repeated after distal blockade of the nerve with 0·5 ml of 1 per cent Xylocaine (Astra Pharmaceuticals Ltd., King's Langley, UK).

Early postoperative measurements

Anal manometry was repeated using the same methodology, as for preoperative measurements, on all 20 patients on the day of hospital dismissal, usually the tenth postoperative day Anal canal resting pressure, maximum squeeze pressure and squeeze increment were measured. The rectoanal inhibitory reflex and the presence of rectal sensation were sought in the same manner as in the preoperative study

Late postoperative measurements

Anal manometry was repeated 6–12 months after operation in 15 patients. Of the original 20 patients, one had died, two had been given a protective transverse loop colostomy and were excluded, and two patients had been operated on <6 months before the time of most recent follow-up

Continence grading

Continence was graded from 1 (perfect) to 5 (requiring colostomy) as previously described[28].

Results

Preoperative and postoperative measurements

Resting and maximum squeeze anal canal pressures fell after operation and did not recover within 6 months The decrease in maximum squeeze pressure was not associated with a significant decrease in the squeeze pressure increment (*Table 1*). The rectoanal inhibitory reflex was present in 19 of 20 patients before operation, but was absent in 19 of 20 patients at discharge from hospital The reflex was identified in one of 15 patients ≥6 months after operation. The presence of the reflex in this case is probably explained by stimulation below the anastomosis. Rectal sensation, present in all patients before operation, was also present after operation.

Table 1 *Resting and maximum squeeze anal sphincter pressure and the pressure increment with squeeze effort in patients before and after low anterior resection and at follow-up ≥6 months after operation*

	Mean(s.e.m.) pressure (mmHg)		
	Preoperative ($n=20$)	Postoperative ($n=20$)	Follow-up ($n=15$)
Maximum resting pressure	67 (4)	51 (4)*	53 (5)*
Maximum squeeze pressure	103 (7)	78 (6)*	85 (7)*
Squeeze increment	35 (4)	27 (4)	31 (4)

4	Frequent major soiling	0	
5	Incontinent (required colostomy)	1	

Intraoperative measurements

There was a significant drop in resting anal canal pressure measured in the anaesthetic room before induction and that measured following induction of anaesthesia (*Table 2*). Division of the inferior mesenteric artery at its origin, full mobilization of the rectum and mesorectum, and transection of the rectum did not affect the resting anal canal pressure (*Table 2*). Construction of a colorectal anastomosis by the EEA instrument inserted from below ($n=5$) was associated with a significant reduction in resting anal pressure (mean(s.e.m.) before anastomosis 40(5) mmHg; after anastomosis 27(4) mmHg; $P<0·05$). In each case, resting anal pressure fell after anastomosis.

Intraoperative nerve stimulation

Stimulation of the presacral nerves after rectal mobilization produced, in four of six patients, a transient inhibition of resting anal sphincter pressure (mean (s.e.m.) 10(2) mmHg). The inhibitory effect lasted 10–20 s, after which resting pressure slowly returned to prestimulation values, despite continued stimulation. The inhibitory effect was successfully blocked by infiltration of the presacral nerve with 0·5 per cent lignocaine distal to the point of stimulation.

Continence grading

The quality of faecal continence was recorded in 15 patients ≥6 months after operation (*Table 3*). Twelve patients considered that they had perfect continence. Two patients had faecal continence difficulties, the first requiring a permanent colostomy. This result, in a multipara, might have been predicted by preoperative manometry as the squeeze increment was only 10 mmHg. Intraoperative injury to the internal anal sphincter contributed to the poor outcome in the other patient in whom resting anal pressure fell from 40 mmHg preoperatively to 16 mmHg postoperatively and 18 mmHg at 6-month follow-up. In this case, a transient decrease in squeeze increment was also observed, but intermittent minor incontinence persisted after recovery of the squeeze increment to preoperative values.

Discussion

In health, faecal continence is maintained by a combination of the sphincteric and reservoir functions of the anal canal and rectum[29]. Other factors that contribute to continence are colonic motility, the anorectal angle and the volume and consistency of healthy stool. No single component of this complex arrangement appears to be all-important. However, functional reserve is obviously less if there has been impairment of sphincter function or reduction of reservoir capacity.

This study has concentrated on the effect of sphincter-saving resection on the anal sphincter component, and particularly on the internal sphincter component of the continence mechanism. After operation, both resting and maximum squeeze pressures in the anal canal were reduced. However, there was no reduction in pressure increment with squeeze effort, an observation which suggests that the effect of sphincter-saving resection is primarily on the internal anal sphincter. This effect may be permanent as 6–12 months after operation resting and maximum squeeze pressures are still reduced.

The mechanism of injury to the internal anal sphincter may be direct, or indirect to the innervation. The internal anal sphincter receives sympathetic motor innervation from the fifth lumbar segment of the sympathetic trunk which passes via the presacral nerves to the pelvic plexus. The parasympathetic motor supply comes from the second, third and fourth sacral nerves, which pass via the nervi erigentes to the pelvic plexus. Presacral mobilization of the rectum or division of the lateral ligaments of the rectum could interrupt either element of autonomic motor innervation[30]. The internal anal sphincter may also be supplied by myenteric nerves connected with the myenteric plexus of the distal colon and rectum[31]. The latter are influenced by sympathetic and parasympathetic nerves accompanying the inferior mesenteric artery and its branches. Division of the inferior mesenteric artery or transection of the rectum could alter mesenteric innervation of the internal sphincter.

Intraoperative recording of resting anal sphincter pressure was performed to elucidate whether injury to the nerve supply of the internal anal sphincter occurred during anterior resection. The results suggest that division of the inferior mesenteric artery, mobilization of the rectum anterior to the fascia of Waldeyer, and transection of the rectum have no effect on resting anal canal pressure. Indeed, stimulation of the presacral nerve following rectal mobilization produced an inhibitory effect in four of six patients. This effect, probably due to β-adrenergic inhibition of the internal anal sphincter[32], has been previously documented in patients undergoing resection or rectal mobilization for benign disease[27,33]. It is now shown to be preserved in at least some patients after rectal mobilization for cancer. Thus the sympathetic supply from the pelvic plexus to the internal sphincter does not run in the mesorectum. Failure to demonstrate inhibition in two patients may represent technical error or damage to the pelvic plexus. The resting pressures in these two patients were similar to those of others in the study.

Measurement of resting anal sphincter pressure after completion of the colorectal anastomosis using a transanal EEA stapler showed a significant reduction in pressure. This implies that insertion of the stapler, which we have noted sometimes requires significant dilatation, stretches the sphincter mechanism reducing resting pressure in the same manner as a Lord's procedure[34]. While this conclusion is at variance with a recent study, which showed no significant effect of controlled anal dilatation on resting anal pressures[35], a similar mechanism of injury has been suggested in patients undergoing ileal pouch–anal anastomosis with mucosal proctectomy during which considerable stretching of the anal sphincters occurs[21]. Indeed, use of an EEA stapler in patients undergoing ileoanal anastomosis without complete mucosal proctectomy is also associated with a fall in resting anal sphincter pressure, albeit less than that seen after complete mucosal proctectomy[36].

The clinical significance of reduced resting anal sphincter pressure after sphincter-saving resection is unclear. A number of investigators have documented a decrease in resting pressure in patients after anterior resection and coloanal anastomosis compared with age-matched controls[13,22,37]. A recent study examined 13 patients before and after low anterior resection and also documented a significant decrease in resting sphincter pressure[18]. However, none of these studies has shown a significant relationship with continence. By contrast, patients with impaired continence after ileal pouch–anal anastomosis have reduced resting anal canal pressure compared with continent patients and healthy controls[21]. It is probable that the larger volume of semisolid stool after ileoanal anastomosis places a greater strain on the continence mechanism than is present after resection. Thus damage to the internal anal sphincter is more likely to result in continence difficulties after ileoanal anastomosis than after resection.

The rectoanal inhibitory reflex was abolished in most patients in this study and did not return within 6 months. These findings are similar to those of Pedersen *et al.*[18], but contrast with other reports[13,14,16] in which the reflex was either preserved or seemed to return with time. Myenteric plexus regeneration across the anastomosis has been suggested as an explanation[14]. This is conceivable after hand-sewn anastomosis, but is unlikely after an inverted EEA stapled anastomosis. Absence of the anorectal inhibitory reflex did not appear to impair continence in this study.

Sphincter-saving low anterior resection has become the preferred surgical treatment in the majority of patients with carcinoma of the middle and lower thirds of the rectum. Preservation of continence while providing a safe and, where possible, curative procedure is the essence of this procedure.

We have shown that full mobilization of the rectum is possible without injury to the presacral innervation of the internal anal sphincter. Preoperative manometry should be considered in patients under consideration for sphincter-saving resection, particularly in multipara as internal sphincter damage caused by stretching, superimposed upon an already compromised external sphincter, may result in impaired continence.

Acknowledgements

We are grateful to Mr Noel McCarthy for help during nerve stimulation studies, to our anaesthetist colleagues and theatre nursing staff, and to Ms Ann Hayes-MacSweeney for secretarial assistance.

Announcement

Association of Surgeons in Training

Membership of the Association is open to all senior registrars holding accredited posts in general surgery, urology, plastic surgery, neurosurgery, orthopaedics, cardiothoracic surgery and paediatric surgery Registrars in the above specialties who are 2 years post-fellowship may also apply. The Association represents the views of members on all matters relevant to surgical training besides holding scientific and social meetings. If you are not a member please contact the Secretary, Andrew McIrvine, 35, Elsie Road, Dulwich, London SE22 8DX, for details of membership, local representatives and forthcoming meetings. The next AGM will be held in Cardiff from 21–23 September 1989: for information contact Mr B. J. Harrison, Department of Surgery, Cardiff Royal Infirmary, Newport Road, Cardiff CF2 1SZ, UK.

Road London W12 0NN, UK

The adaptive response of the large bowel to surgical defunction in man is essentially unknown, although in the rat there is progressive hypoplasia and a reduced propensity to experimental carcinogenesis. Mucosal biopsies were taken from the upper rectum completely defunctioned by a proximal stoma from 2 months to 5 years earlier in 11 patients and from 14 controls without abdominal operations or disease. Samples were established in organ culture and, after 16 h, crypt cell production rate (CCPR) was determined by a stathmokinetic technique. Crypt morphometry was also undertaken. CCPR in defunctioned large bowel was less than half that of controls: (mean (s.d.) 1·96 (0·68) versus 4·65 (0·54) cells crypt^{-1} h^{-1}, P<0·0001). Likewise, crypt length was 24 per cent lower (0·34 (0·05) versus 0·44 (0·04) mm, P<0·0001) and crypt width was 38 per cent lower (0·04 (0·01) versus 0·07 (0·01) mm, P<0·0001). Rectal defunction causes profound and persistent hypoplasia in man.

Keywords: Rectal hypoplasia, defunctioning colostomy, crypt cell proliferation rate

Temporary defunction of the large bowel, by proximal colostomy or ileostomy, is commonly performed to 'protect' a low anastomosis, to 'rest' the intestine in inflammatory bowel disease, and as an alternative to anastomosis in emergency procedures for colorectal obstruction and perforation Very little is known about cytokinetic changes in a defunctioned large bowel segment, although it is recognized that the blind loop of small bowel in patients with jejunoileal bypass probably undergoes atrophy and villous hypoplasia after exclusion from the luminal stream[1]. In man there is a single report of marked mucosal atrophy in a defunctioned rectum[2].

In the rat both the colon and the small intestine are as sensitive to surgical defunction as they are to withdrawal of food, undergoing progressive hypoplasia in each case[3,4]. Mucosal mass and crypt cell production rate (CCPR) in the left colon are halved within a month of proximal defunctioning colostomy[5-7], and crypt depth is reduced by 18 per cent in a colonic Thiry–Vella fistula[7] Colon atrophies rapidly during the first week of defunction and then at a slower rate for a further 3 weeks[5]. Bulk may be more important than nutrient content in maintaining colonic mucosal integrity, in this respect the colon differs from the small bowel[4,8] Low residue diets are antitropic, i e they diminish mucosal mass, even if caloric intake is kept constant[9]. Instillation of faeces into a colonic Thiry-Vella fistula partly restores normal mucosal mass[7].

In view of the close association between rates of colonic cell turnover and susceptibility to neoplasia[10], measuring parameters of adaptation in the human large bowel is becoming increasingly relevant to the understanding of colorectal carcinogenesis[11] In this study, CCPR and crypt size were used to assess adaptation in the defunctioned rectum of 11 patients. Results were compared with those in 14 controls.

Patients and methods

Eleven patients who had undergone defunction of the colorectum by proximal colostomy ($n=8$) or ileostomy ($n=3$) were studied Fourteen controls presenting to the outpatient department with no known colorectal (as opposed to anal) disease were also investigated The commonest diagnosis in controls was haemorrhoids (64 per cent); five patients had non-specific abdominal pain for which no cause could be found (*Table 1*) Eight (73 per cent) of those with a defunctioned rectum had undergone Hartmann's procedure (*Table 2*) In five of these diverticular disease was the underlying lesion (with a vesicocolic fistula) and three had had colonic carcinoma The remaining three patients had a defunctioning ileostomy for various indications. Patients and controls were of similar mean (s d) age (59·7 (13 8) *versus* 61 2 (17 1) years) and the sex distribution was roughly equivalent Defunction had been carried out 2–62 months before this study (median 4 months)

Biopsies

After fully informed consent was obtained, a sigmoidoscopy was carried out and two biopsies were taken from the upper rectum (or close to the blind end of the rectal stump) with Patterson® biopsy forceps (Downs Surgical Ltd , Sheffield, UK) Biopsies were then placed into ice-cold RPMI 1640® medium (Gibco, Paisley, UK) and were transported

to the organ culture laboratory. To avoid diurnal fluctuations in cell turnover rates[12,13], all sigmoidoscopies were performed in the early afternoon between 14.00 and 15.00 hours

Organ culture

Organ culture was carried out by the method of Trowell[14] modified by Allan and Jewell[15]. Rectal samples were oriented on a cork board and were divided into $2\,mm^2$ explants using a razor blade. Great care was taken to prevent samples drying by keeping them moist at all times Explants were placed mucosal surface uppermost on the triangular stainless steel grids of circular organ culture dishes. Each grid supported three to four explants. The organ culture medium was equilibrated with 95 per cent oxygen and 5 per cent carbon dioxide at 37°C for 1 h before use. Culture medium was RPMI 1640 (containing 25 mM Hepes buffer, 2 mM glutamine, 24 mM sodium bicarbonate) 90 per cent volume/volume, plus heat-inactivated fetal calf serum 10 per cent volume/volume Penicillin (100 units ml^{-1}) and gentamicin (40 μg ml^{-1}) were added to the final medium, which had a pH of 7·22–7·28 Medium was passed through a 0·22 μm millipore filter before being added to the central well of the dish. After adding medium (approximately 1 ml) the grid's surface was covered with fluid, but biopsies were not submerged. Cotton wool soaked in normal saline was placed in the outer well of the culture dishes to create a moist atmosphere Explants were then cultured in a gas-tight jar at 37°C in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide

Stathmokinetic method

Our method of measuring cell proliferation in mucosal biopsies maintained in organ culture has recently been described[16] In brief, vincristine 0·5 μg ml^{-1} was added to the medium after 16 h culture Samples removed sequentially over the next 40–180 min were fixed in Carnoy's fluid for 4 h and then stored in 70 per cent alcohol Specimens were later stained by the Feulgen method for DNA, the muscle layer was stripped away and individual crypts were separated out under a dissecting microscope by microdissection[17]. The number of arrested metaphase figures in 15 crypts per sample was recorded, and the mean value was plotted against time after vincristine administration. The slope of the regression line so formed gives the CCPR in cells per crypt per hour (Reference 12).

Crypt morphometry

During microdissection the total length of 30 whole crypts per sample was measured by ocular micrometry. The crypt width was similarly measured at the mid-point along the length of the crypt.

Results

CCPR (Figure 1)

As previously seen[16], most samples were well preserved after 16–19 h of culture. It was impossible to measure CCPR in five controls (36 per cent) and four defunctioned patients (36 per cent) owing to unsatisfactory culture recognized by crypt necrosis. Among the remaining healthy biopsies, CCPR in seven patients with a defunctioned rectum was less than half that of the nine controls (mean (s d.) 1·96 (0·68) *versus* 4·65 (0·54) cells $crypt^{-1} h^{-1}$, $P<0.0001$). There was no correlation between CCPR and either age or length of time since defunction. There was no difference between counts obtained from crypts at the periphery of the specimens compared with those from the central regions. Indeed, if central necrosis was detected the specimens were discarded.

Crypt morphometry (Figure 2)

In patients with a defunctioned rectum, crypt length was 24 per cent less than that of controls and crypt width was 38 per cent less

Discussion

Striking morphological and cytokinetic changes occur in the human large bowel after defunction. As in animal experiments when sections of the large bowel are isolated from the luminal stream by proximal colostomy[6] or Thiry–Vella fistula[7], CCPR falls to less than half that of control values. Reduction in CCPR in man is sustained for at least 5 years after defunction. This persistent hypoplasia contrasts with the preliminary data reported by Winslet and colleagues[18], who found that 2 weeks after defunction CCPR was 35 per cent of initial values but by 12 weeks it had returned to normal. The present finding is in line with our own experimental work in rats[5–7].

The long-term reduction in CCPR found in two patients with ileostomies for inflammatory bowel disease is interesting as it provides an explanation for the mucosal recovery that can follow diversion of the faecal stream. Intact rectum in ulcerative proctitis shows increased CCPR whether the disease is in remission or relapse[19]. Carcinomas can still form in the defunctioned rectum in patients with ulcerative colitis[20] and in small bowel loops bypassed for Crohn's disease[21]. Perhaps in

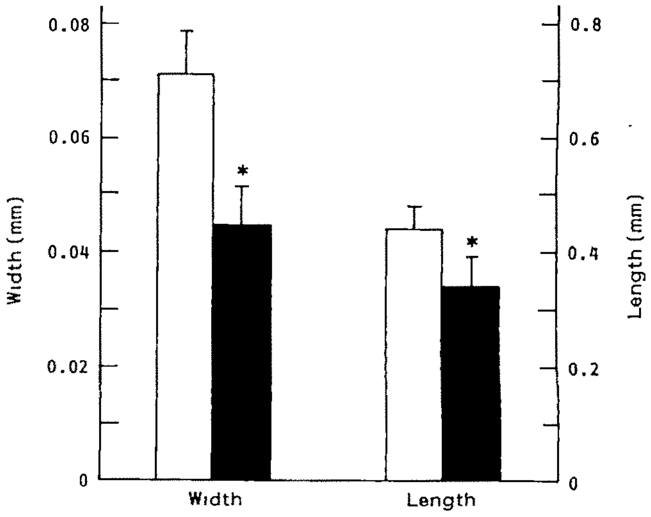

Figure 2 *Crypt morphometry in control (□) and defunctioned (■) rectal mucosa, * P <0·001 (control* versus *defunctioned mucosa). The mean and standard deviation are shown for crypt length and width*

such patients the co-carcinogenic stimulus of the underlying disease is so strong that it overcomes the antitropic effect of defunction, similar to the effect we have observed at a defunctioned anastomosis[22]. Alternatively, different mucosal kinetics may apply, possibly because of bacterial contamination.

Although morphometric parameters are not a very reliable index for quantifying adaptation[23], measurements made in microdissected crypts showed considerable crypt atrophy in defunctioned mucosa. Crypt morphometry has not previously been described in individual microdissected crypts. It is our subjective impression that the rectal stump is shrunken and atrophic after Hartmann's procedure, a finding that is strikingly apparent in the rat[6,7]. Mucosal hypoplasia is therefore involved in this process in man. The present study lends support to the single observation by Shaw-Dunn and Wright[2] of reduced mucosal (and muscularis) volume in the rectal stump excised 35 years after defunction for presumed ulcerative colitis. Thus large bowel excluded from the luminal stream behaves in a similar fashion to small bowel.

Although several patients with a defunctioned large bowel had had pathological processes (carcinoma, colitis) known to affect mucosal cytokinetics, such diseases are unlikely to have been the mediator of the 58 per cent fall in CCPR observed Cell birth rates in tumours are generally thought to be slower than those in normal epithelium[24], but two recent studies have shown that in patients with colorectal carcinoma or adenoma there is an increased rate of DNA synthesis throughout the whole colon, indicating a 'field change'[25,26]. Moreover, patients at high risk of developing cancer have wider proliferation zones in their colonic crypts ('phase 1' lesions)[11].

Organ culture studies in ulcerative proctocolitis nearly all show enhancement of CCPR[19,27] A recent study in Crohn's disease failed to show a raised CCPR, although the expected fall in CCPR after defunction did not occur[28]. It is likely, therefore, that the underlying disease process in the five patients with cancer or inflammatory bowel disease would tend to raise, rather than to lower, CCPR.

After colostomy closure in animals there is a rapid return to normal rates of cell turnover[5]. In man the process may take up to 3 months[28]. The high incidence of diarrhoea observed after colostomy closure may be due partly to the functional impairment that accompanies hypoplasia[7,29]. Functional adaptation of the colon is known to occur in rats, although evidence is scanty. Using a colonic perfusion model, Urban and colleagues[30] showed that net transport of electrolytes increases after enterectomy. This effect seems to be proportional to increases in mucosal cell mass rather than increased absorptive capacity of individual cells[30], and it is maximal in the caecum[31]. It might thus be expected that exclusion from the luminal stream would lead to a functional deficit. Conflicting reports abound concerning the correct timing of colostomy closure[29,32]. Early closure might reduce diarrhoea[29] but could conceivably promote metachronous carcinogenesis[33].

Rats with colonic cancer were given a palatable liquid diet which enabled them to gain weight while those fed on stock diet, either ad libitum *or in restricted amounts, lost weight. Protein synthesis was measured* in vivo *using a flooding dose technique. Increased nutrient intake caused increases in the rate of protein synthesis in muscle, liver and non-diseased parts of the colon, but had no effect on protein synthesis in the tumours. These data suggest that enteral hyperalimentation may be safely employed in the preoperative management of patients with cancer, as it is likely to stimulate nitrogen retention in the host tissues without increasing the growth rate of the tumour.*

Keywords: Protein synthesis, cancer, nutritional support

Patients who are admitted to hospital for surgical treatment of gastrointestinal cancer are often malnourished[1,2]. Because malnutrition is believed to lead to increased risk of postoperative complications[3,4], it has been recommended that such patients should be given nutritional support for up to 2 weeks before the operation[5,6]. However, there is some concern that nutritional support may enhance the growth of the tumour[7]. It would clearly not be appropriate to give nutritional support if this was found to stimulate tumour growth more than repletion of host tissues.

One of the most prominent features of the malnutrition seen in cancer patients is wasting of skeletal muscle, and this has now been shown to be associated with a reduced rate of synthesis of muscle protein[8,9] Moreover, muscle represents up to 70 per cent of lean body mass, and changes in muscle protein synthesis are believed to be an important determinant of changes in protein metabolism in the body as a whole[10]. Thus, an increase in the rate of synthesis of muscle protein would be an early sign of reversal of the wasting process and hence an improvement in the patient's nutritional status.

We have made *in vivo* measurements of rates of protein synthesis in muscle and other tissues of rats with colorectal cancers. The rate of protein synthesis in the tumours has been measured to see whether they respond to increased nutrient intake. Nutritional supplementation was achieved by offering a liquid diet which was found to cause a spontaneous increase in food intake in these rats.

Materials and methods

Colorectal tumours were induced in female Wistar rats (Tuck and Son, Battlesbridge, UK) by repeated subcutaneous injections of dimethylhydrazine. The dose was 40 mg/kg body weight per week for 10 weeks and the method of preparation was that of Filipe[11] Signs of tumour presence, such as rectal bleeding, diarrhoea and abdominal distension, appeared after approximately 6 months.

Experiment 1

Eight symptomatic cancer bearing rats, of mean (s d) weight 315(5) g, were randomly allocated to receive either stock diet (41B*, BP Nutrition Ltd , Witham, UK), at a fixed rate of 10 g per day, or a liquid formula diet (Nutrauxil®, KabiVitrum, Stockholm, Sweden) fed *ad libitum*. Water was supplied to both groups *ad libitum* Rats were housed individually and food intake was measured each day for 7 days, after which protein synthesis rates were measured

Experiment 2

Eight symptomatic cancer bearing rats, of mean (s.d) weight 333(11) g, were randomly allocated to receive either stock diet (41B) or a liquid formula diet (Ensure®, Abbott Laboratories Ltd., Queenborough, UK) Both groups received food and water *ad libitum* Rats were housed individually and food intake was measured each day for 5 days, after which protein synthesis rates were measured.

Protein synthesis measurements

The method of Garlick *et al.*[12] was used to measure the rate of protein synthesis *in vivo* in the tumours, as well as in quadriceps and rectus abdominis muscles, in liver, and in parts of the colon not directly affected by tumour growth This involved injection of a flooding dose (150 μmol and 50 μCi (1·8 MBq) in 1 ml per 100 g body weight) of L-phenyl[2,3-^{3}H]alanine via a lateral tail vein, and killing the animals by decapitation 10 min later Tissues were rapidly cooled in iced water, removed, and stored frozen in liquid nitrogen. The fractional rate of protein synthesis was calculated from the ratio of specific radioactivities of free and protein bound phenylalanine measured by the specific, enzymatic assay

Statistics

Results were expressed as means with their standard errors, and statistical comparisons were made using Student's two-tailed t test for unpaired data.

Results

Weight gain and food intake (Tables 1 and 2)

Feeding the highly palatable liquid diets caused the rats to increase their intake of protein and energy above their *ad libitum* intake of conventional stock diet (experiment 2) as well as above the restricted intake of stock diet employed in experiment 1. This allowed the rats to gain weight, in contrast to both groups of stock diet fed rats which lost weight.

Protein synthesis rates (Tables 3 and 4)

The rate of protein synthesis in two different skeletal muscles was increased by supplementary feeding in both experiments, although the difference did not quite reach statistical significance in the case of quadriceps in experiment 1. This suggests that the low rates of muscle protein synthesis which have been observed in human patients with cancer[9] may be at least partly caused by low food intake, and might be improved by increasing food intake.

Rates of protein synthesis in liver and colon were increased by supplementary feeding in experiment 1 but not in experiment 2. Apparently restriction of food intake in experiment 1 caused a reduction in the rates of protein synthesis in these tissues, and this was reversed by increasing the food intake.

In marked contrast to the effects on host tissues, supplementary feeding had no effect on the rate of protein synthesis in the tumours in either experiment. This suggests that protein synthesis for tumour growth was not limited by substrate supply, and indeed the tumours may already have been synthesizing protein at a maximal rate.

Discussion

Two different liquid diets were used in the two experiments in order to confirm that the effects observed were caused by increased nutrient intake rather than some qualitative aspect of the dietary supplement. Voluntary intake of both energy and protein reached approximately the same level in the supplemented animals in the two experiments, as did rates of tissue protein synthesis.

Reliable measurement of rates of tissue protein synthesis using isotopically labelled amino acids requires accurate measurement of the isotopic enrichment of the precursor pool as well as the protein product. This was achieved in the present experiments by injecting a flooding dose of tritiated phenylalanine[12]. The values we have determined for the rates of protein synthesis in colon, liver and muscle in nutritionally supported animals compare well with other published values for rats of this age[13–15]. Values for the rate of protein synthesis in colonic tumours in rats have not previously been reported.

Quadriceps and rectus abdominis muscles were chosen as representative of skeletal muscle in the body as a whole because they are both of mixed fibre-type composition and their response to malnutrition has been shown to be typical of that of hindlimb and trunk muscles respectively[16]. Interestingly, the difference in magnitude in protein synthesis rate between the two groups was slightly greater in the rectus abdominis than the quadriceps, and the data of Spence and Hansen-Smith[16] suggest that trunk muscles lose more protein in response to severe undernutrition than do limb muscles.

Table 4 *Fractional rates of protein synthesis in tissues of cancer bearing rats fed* ad libitum *on liquid diet (supplemented) or on stock diet (control) for 5 days experiment 2*

It is known that food supply is an important factor regulating the rate of protein synthesis in muscle in the rat[17] and in man[10] under normal circumstances. We have previously shown that the rate of muscle protein synthesis in tumour bearing animals is reduced partly as a result of their low food intake[18]. The present results suggest that cancer does not prevent muscle, and indeed other tissues, from responding to increased nutrient intake with an increase in the rate of protein synthesis. We have, in fact, previously reported an increase in the rate of protein synthesis in muscle and in the whole body in patients with gastrointestinal malignancies who were given supplementary enteral nutritional support before operation[19]

An increase in protein synthesis would be expected to lead to improved maintenance of lean body mass Moreover, improvement in muscle mass, particularly of the respiratory muscles, could have a direct clinical benefit, as it has been suggested that wasting of the respiratory muscles, and the consequent inability to overcome respiratory infections, may be a very common cause of morbidity and mortality amongst cancer patients[9] It is known that muscle wasting caused by disease or malnutrition affects respiratory muscles to the same extent as other skeletal muscles[20]

Preoperative nutritional supplementation in patients with gastrointestinal cancers has been shown to reduce the subsequent incidence of wound infections[5], major complications and mortality[6]. In both these studies the nutrients were supplied intravenously and it has been argued that the clinical benefit which can be achieved is too small to justify the expense and the risk of catheter-related sepsis involved in such treatment The enteral route is a cheaper and less hazardous way of providing nutritional support and this should be equally beneficial for patients who retain a functioning gut. We have now shown that it is not likely to cause an unwanted stimulation of protein synthesis, and hence growth, in the tumour.

Fatty tumours of the large intestine: a clinicopathological review of 13 cases

J. Ryan, J. E. Martin and D. J. Pollock

Department of Morbid Anatomy, The London Hospital, London E1 1BB, UK
Correspondence to:
Dr J. Ryan, Department of Histopathology, Chestnut Villa, Severalls Hospital, Colchester, Essex CO4 5HG, UK

Thirteen cases of benign fatty tumours of the colon have been reviewed. There were ten instances of submucosal lipoma, two of which were multiple, and three of lipohyperplasia of the ileocaecal valve. Abdominal pain and gastrointestinal bleeding were the commonest symptoms. Barium enema and angiography were misleading, the former in confusing polypoid lipomas and protruberant ileocaecal valves with carcinoma, the latter in misinterpreting fatty tissue vasculature as angiodysplasia in three patients. Most lesions were in the right side of the colon, and many were treated by limited colectomy as if for carcinoma or angiodysplasia. No patient has died as a result of their disease. Awareness of the possibility of colonic lipomas and knowledge of the normal ileocaecal valve anatomy are of importance to radiologists and endoscopists, particularly now that angiography is localizing the smaller fatty lesions.

Keywords: Lipoma, large intestine, ileocaecal valve

Although lipomatous lesions are the second commonest benign tumour of the large bowel, they are relatively uncommon in clinical practice. With the advent of colonoscopy and selective angiography the type of fatty lesion resected is changing. In this review we document our experience.

Patients

A review of the surgical pathology files at the Institute of Pathology at the London Hospital over a 50-year period revealed 13 cases of fatty lesions in the large intestine (*Table 1*). Nine of these were resected in the 10-year period up to 1987. There were eight women and five men, and their ages ranged from 35 to 78 years, with a mean of 59 years.

Investigations included barium enema (seven cases) and colonoscopy (seven cases), with selective superior mesenteric angiography (*Figure 1*) performed in three (cases 9, 10, 12). The preoperative diagnoses recorded included carcinoma of the colon in five, angiodysplasia or other vascular malformation in three and one intussusception of unknown cause.

Eight patients underwent a limited colectomy, while the remaining five cases had removal of the nodule with the overlying mucosa.

The histological diagnosis was submucosal lipoma in ten (five men, five women, mean age 53 years) and lipohyperplasia of the ileocaecal valve in three cases (all women, mean age 73 years).

We describe one patient (case 12 in *Table 1*) in detail to illustrate the problems in diagnosis of gastrointestinal blood loss. This woman had a Starr–Edwards aortic valve replacement for aortic valve disease in 1977 at the age of 57 years and was put on long term anticoagulation therapy. In 1982 after some melaena a diagnosis of duodenal ulcer was made. She had further melaena and in 1987 a diagnosis of caecal angiodysplasia was made following selective superior mesenteric angiography. After two unsuccessful attempts at colonoscopic cauterization of the lesion she underwent a right hemicolectomy. Pathological examination showed lipohyperplasia of the ileocaecal valve with many ectatic blood vessels in the adipose tissue and overlying mucosa but no ulceration or apparent site of blood loss into the bowel. Her melaena persisted and gastroduodenoscopy showed a small duodenal erosion which was cauterized. It was decided to replace the Starr–Edwards aortic valve with a xenograft so that the patient could come off warfarin. In late 1987 a Carpentier–Edwards bioprosthesis was inserted. Subsequently she has remained well with no further blood loss from the gastrointestinal tract.

Results

On macroscopic examination the submucosal lipomas had a lobulated yellow-white appearance, and most were greater than 2 cm in diameter. In these larger ones, particularly those associated with an intussusception (*Figure 2*), there were varying degrees of necrosis. Many of the larger lipomas were polypoid, with ulceration of the overlying mucosa. Microscopically there was normal adipose tissue, with fat necrosis and granulation tissue in the larger intussuscepted and traumatized cases. Postresection angiography was performed on two of the specimens where angiodysplasia was suspected. Ectatic blood vessels within the fatty tissue were seen in some, but in none was a site of blood loss identified.

All three patients with lipohyperplasia of the ileocaecal valve showed thickening and pouting of the valve which protruded into the caecum (*Figure 3*). Angiography was performed on the resected specimen in case 12 where angiodysplasia was suspected. Microscopically there was excessive fatty tissue in the submucosa, with ectatic blood vessels distributed through it and extending up to the mucosa. There was no ulceration. No other sites of bleeding or of angiodysplasia were demonstrated in the resected specimens.

Discussion

Lipomas of the large bowel were initially described by Bauer in 1757[2,3], although it was not until 1909 that Stetten[4] emphasized that they can clinically mimic colonic carcinoma. In 1985 Hall *et al.*[1] using case 9 illustrated how they can mimic angiodysplasia.

The incidence of lipoma of the colon has been reported from autopsy series to range from 0·035 to 4·4 per cent[5,6]. Mayo *et al.*[7] reviewed surgical material exclusively: out of 4000 cases of benign neoplasms of the gastrointestinal tract they found 164 (4 per cent) lipomas. Most involved the ileocaecal valve and large bowel; the stomach and proximal small bowel were less commonly affected.

The size of the lipoma is important[2,6–10], and only those over 2 cm, as were most of those in our series, produce symptoms. The commonest symptoms were bleeding per rectum and abdominal pain, similar to the reported findings. The rectal bleeding was in general related to the smaller lesions, whereas abdominal pain was related to episodes of intussusception or intestinal obstruction associated with the larger, frequently polypoid lipomas. Lipomas of the colon have usually been reported to be from 1·5 to 2 times more common in women[10].

* Reference 1

Lipomas of the large bowel may be submucosal, subserosal or intermucosal–serosal. In the literature the first type is commonest (90 per cent of large bowel lipomas) and this too is our experience. The most common site is the right side of the colon.

Many lipomas in this series were removed because they were suspected of being carcinomas. Differentiation between the two may be difficult but is important as the surgical management differs considerably. In general, weight loss and anorexia are associated with carcinoma. Lipomas tend to be located on the right side whereas there is a left-sided predeliction for epithelial neoplasms[11]. Radiological differentiation between the two is difficult, but fatty tumours are radiolucent which may be helpful. Ginzberg *et al.*[12] noted some features which they considered diagnostic: a round or ovoid, lucent, filling defect with smooth margins, frequently lobulated, especially in the right colon. Barium enema studies may demonstrate a mass that changes size and shape (squeeze sign) throughout the examination due to peristaltic bowel movements[13]. Water enemas have been advocated[14,15] to improve the contrast with the radiolucent fat. Computerized tomography is considered by some to be the definitive diagnostic measure in recognizing colonic lipomas[16,17].

Colonoscopy may allow direct visualization of the submucosal lipoma, which may be easily indented with a closed biopsy forceps. The tumour will rapidly spring back to resume its previous shape on withdrawal of the forceps (pillow or cushion sign). Pressure on the lipoma will compress the

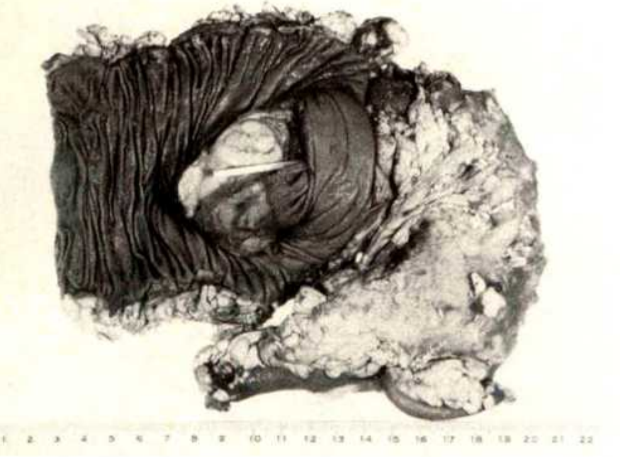

Figure 2 *Case 3 showing colonic intussusception, with white stick marking the lipoma*

overlying superficial vessels to disclose the characteristic yellow coloration of lipid. The mucosa may be grasped with the forceps and pulled up, lifting it like a tent away from the lipoma. If the surface mucosa is removed from one site by repeated biopsy from the same location (well technique), fat may be seen protruding from the biopsy site. This 'naked fat sign' is considered pathognomonic of a lipoma[18]. While colonoscopy is reliable for the diagnosis of the usual lipoma, when the lesion is atypical, firm or ulcerated it is more difficult.

In two of our cases (cases 8 and 9) the diagnosis was multiple lipoma. The incidence of multiple lipoma varies in the reported series. Haller and Roberts[2] found only 20 cases reported in the literature up to 1963, although Castro and Stearns[8] found 11 patients (24·4 per cent) in their review of their own material. Khawaja[19] states that in 10 per cent of cases lipomas are multiple.

The management of symptomatic colonic lipomas is dependent on their size and location, with consideration given to the possibility of intussusception if left untreated. Treatment varies from hemicolectomy to segmental resection to local excision, but much is dependent on the correct preoperative diagnosis and the intraoperative findings. Colonoscopic removal of polypoid submucosal lipomas is an established safe method of treatment[20], although in very large lesions the pedicle or stalk may actually be formed by serosal invagination. Snaring and cutting of such a stalk would result in free perforation[19].

The spontaneous expulsion of a lipoma per rectum has been recorded[21], in association with both colonic intussusception[3] and colonic perforation[22].

The aetiology of colonic lipomas is not known. They are usually found in the older patient, but no association has been recorded with diabetes, hyperlipidaemia or other degenerative diseases. An association between Weber–Christian disease and colonic lipomas has been reported[23].

The ileocaecal valve syndrome, where patients have symptoms of bloating, right-sided abdominal pain, and tenderness over the site of the ileocaecal valve, is said to be due to hypertrophy of the ileocaecal sphincter which pouts into the caecum[24]. This may be demonstrable on barium enema examination. Lipomas have been demonstrated on the caecal side of the valve[24]. Three of our cases showed this protrusion of the valve, a feature noted occasionally by endoscopists. The preoperative diagnoses were carcinoma and angiodysplasia. Microscopy showed lipohyperplasia, a diffuse increase in adipose tissue in the submucosa of the valve[25]. Whether this feature is a variation of the normal anatomy of the ileocaecal valve, or deserves the designation lipohyperplasia, is open to question. Haller and Roberts[2] discussed fatty infiltration of the ileocaecal valve, and their Figure 1 demonstrates the difference between a lipoma of the ileocaecal valve and an ileocaecal valve with increased adipose tissue. The presence of a limiting membrane in the former is the mainstay of differentiation between the two. They do not use the term lipohyperplasia. None of our cases was very well circumscribed with a limiting membrane. Lipohyperplasia of the ileocaecal valve is usually a localized manifestation of generalized obesity, although none of our patients was overweight.

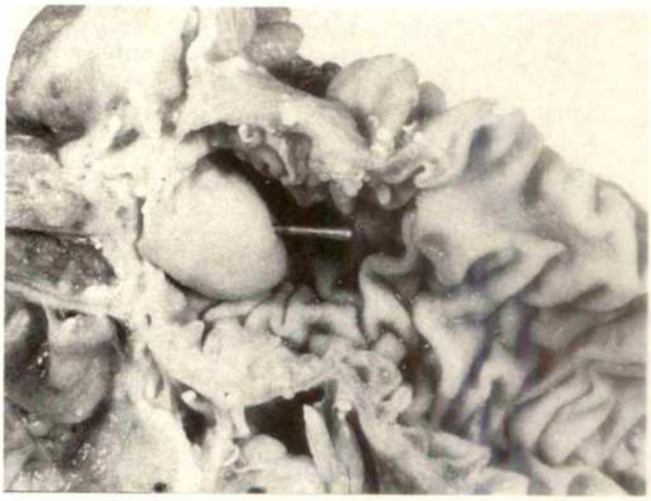

Figure 3 *Case 12: resected specimen with a probe in the bowel lumen*

The ileocolonic junction acts both as a mechanical valve and a functional sphincter[26] and has been studied *in vivo* through a caecostomy[27] and by endoscopic observations[28]. It varies from a labial (flat) form to a papillary form depending on the kinetic state of the bowel. Mimicry of a malignant tumour has been recorded[29].

Case 12 is interesting because of the association of gastrointestinal bleeding with aortic valve disease[30]. The association may be spurious and due to the anticoagulant therapy.

It is notable that in our experience the more recently diagnosed fatty lesions of the colon have been smaller than those previously removed, and they have been picked up by selective angiography. Whether they were the true cause of the rectal bleeding is open to question; however, the recognition of fatty lesions, and their distinction both from angiodysplasia and the variations of anatomy of the ileocaecal valve must be recognized. The radiological criteria for the angiographic diagnosis of angiodysplasia must be rigorously followed[31]. The fact that angiodysplasia most commonly occurs in the caecum makes the radiological distinction between that and the normal or abnormal ileocaecal valve difficult.

Toxic megacolon and perforation caused by Salmonella

K. P. Gill, T. M. Feeley and F. B. V. Keane

Department of Surgery, Adelaide Hospital, Dublin, Ireland
Correspondence to: Dr T. M. Feeley, Department of Surgery, St. James' Hospital, James' Street, Dublin 8, Ireland

Case report

A 41-year-old man was admitted to hospital with a 2-week history of bloody diarrhoea, 10–15 episodes daily. For the previous year he had had numerous similar but less severe episodes. On admission vital signs were normal and the abdomen was soft and non-tender with normal bowel sounds. Stools were positive for occult blood. Stool samples were sent for culture. Twenty-four hours after admission he developed severe abdominal pain and became pyrexic (39°C). An abdominal X-ray showed gross dilatation of the transverse colon and free gas in the peritoneal cavity. Blood cultures were taken; he was commenced on intravenous antibiotics and transferred to the surgical department at our hospital. On admission he was pyrexic (39°C) and his pulse and blood pressure were normal. His abdomen was rigid and silent. Initial investigations showed haemoglobin 9·0 g/dl, white cell count $5 \cdot 4 \times 10^9$/litre, serum albumin 25 g/l, and normal urea and electrolyte concentrations. He was taken to theatre shortly after admission where sigmoidoscopy before laparotomy showed normal-looking rectal mucosa. At laparotomy there was free gas and mild peritoneal contamination.

There were numerous perforations in the transverse colon which was very friable. The ascending and descending colon were diseased to a lesser extent while the lower sigmoid colon and rectum looked normal. The small intestine was normal.

A subtotal colectomy, leaving the sigmoid colon and the rectum, was carried out and an ileostomy and mucous fistula were fashioned. His postoperative course was uneventful. Blood and stool cultures showed *Salmonella Newport* as did the peritoneal fluid taken at the time of laparotomy.

Histology of the resected colon showed severe colitis, possibly ulcerative colitis or Crohn's disease, but consistent with a *Salmonella* colitis.

At outpatient review 2 months postoperatively he was very well; *S. Newport* was grown from ileostomy effluent and rectal biopsy showed normal mucosa. Bowel continuity was restored 3 months after operation and he is well and asymptomatic 2 years later.

Discussion

A small number of colonic perforations due to *Salmonella* have been reported, almost all in association with small bowel perforations[1,2]. This is the first report of colonic perforation caused by *S. Newport*. Although the small intestine is regarded as the principal site affected by *Salmonella* infection, it has been suggested that colonic involvement is frequent and is probably important as a cause of the diarrhoea[3]. Differentiation between *Salmonella* colitis and ulcerative colitis can be difficult as: (1) sigmoidoscopic findings may be identical; (2) toxic dilatation of the colon can occur in both conditions; (3) histological examination in salmonellosis may show florid crypt abscesses and other changes similar to those found in idiopathic ulcerative colitis[4]; (4) *Salmonella* infection can occur in association with ulcerative colitis[5].

In our patient the provisional diagnosis at the time of admission was ulcerative colitis. Because the rectum was normal on sigmoidoscopy and at laparotomy, Crohn's disease was then considered. It should be noted that the rectum is not usually spared in *Salmonella* colitis[3].

This case report shows that not all cases of toxic megacolon are due to inflammatory bowel disease and in the acute situation, when presented with a perforated toxic megacolon in a patient with a history very suggestive of ulcerative colitis, the rectum should be retained.

Collagen changes around intestinal anastomoses in germ-free rats

W. J. B. Mastboom, T. Hendriks and H. H. M. de Boer

Department of General Surgery, St. Radboud University Hospital, PO Box 9101, 6500 HB Nijmegen, The Netherlands

Correspondence to:
Dr W. J. B. Mastboom

The changes in collagen, measured as hydroxyproline, concentration around both ileal and colonic anastomoses in germ-free and control rats have been investigated and compared with each other. The germ-free rats were raised, operated on and maintained under completely pyrogen-free conditions. Animals were killed 2, 3 or 7 days after operation. There was a significant reduction in the lowering of hydroxyproline concentrations around the colonic anastomosis of germ-free rats compared with control rats both in the anastomosis at days 2 and 3 (P = 0·04 and P = 0·006 respectively) and in the proximal segment at day 3 (P = 0·03). In ileal anastomoses, significant differences between control and germ-free rats were only found at 7 days. Here, the increase in hydroxyproline concentration observed in control rats was significantly reduced in germ-free rats. These data are taken to support the hypothesis that bacteria affect colonic anastomotic healing by contributing to postoperative collagen degradation.

Keywords: Germ-free rats, collagen, intestinal anastomosis, wound healing

Dehiscence of large bowel anastomoses is a frequent complication in colonic surgery and is associated with a considerable mortality rate[1]. On the other hand, the leakage rate of ileal anastomoses is low[2]. In order to devise measures to prevent dehiscence, the crucial steps in anastomotic healing should be defined. Comparison of the healing sequence in small and large bowel might be helpful in this respect.

The structural protein collagen is of major importance in maintaining the strength of the intestinal wall. Investigations into the healing of intestinal anastomoses in various animals have shown that massive changes in collagen concentrations occur during the first week after operation[3–5], changes which are more extensive in the colon than in the ileum[6,7]. It is generally believed that immediately after operation collagen degradation occurs, followed by *de novo* synthesis. This 'collagenous equilibrium' is thought to be of paramount importance in undisturbed healing[8].

An obvious difference between small and large bowel is the increased presence of micro-organisms in the latter. As bacteria are capable of producing collagenolytic enzymes[9], they might enhance postoperative collagen degradation and consequently affect anastomotic healing. Thus, it is of interest to examine the behaviour of collagen under conditions where bacteria are completely absent during operation and subsequent healing.

For this purpose, we have compared changes in collagen concentrations around intestinal anastomoses in germ-free rats with those found in normal rats.

Materials and methods

Animals

Two groups of male Wistar rats were used: 30 control rats (average weight 244 g) and 45 germ-free rats of similar age and weight. They were fed a standard diet (Hope Farms, Woerden, The Netherlands) and allowed water *ad libitum*.

The germ-free rats were born and raised under sterile conditions[10]. Immediately before operation the animals were moved, taking full precautions against bacterial contamination, from quarantine to a cage in a horizontal laminar flow workstation, where the operation was performed under pyrogen-free conditions. The animals remained in the same place until they were killed. Before operation and before killing the rats, faecal samples were taken for culture. All preoperative samples were negative. However, 20 of the 45 faecal samples taken before killing the rats showed bacterial contamination. These animals were excluded from the series. Thus 25 germ-free rats remained which were killed 2 ($n = 7$), 3 ($n = 11$) and 7 ($n = 7$) days after operation. The three comparable control groups, operated on under non-sterile conditions, consisted of ten animals each.

Operative procedure

Operations were performed as described previously[11]. Briefly, anaesthesia was induced with sodium pentobarbital, a median laparotomy was performed and 1 cm of both the ileum and the colon were resected at 15 cm proximal to the ileocaecal junction and 3 cm proximal to the rectal peritoneal reflection respectively. An inverting one-layer end-to-end anastomosis was constructed using a microsurgical technique. After 2, 3 or 7 days the rats were killed by an intracardiac overdose of sodium pentobarbital. Both anastomoses were dissected out and cleaned from surrounding tissue. Three 1-cm samples were collected, one containing the anastomosis in the middle and the others comprising the adjacent proximal and distal segments. These postoperative sections of bowel were compared with the control segment removed during operation. In this way each animal served as its own control.

All samples were frozen immediately and stored in liquid nitrogen until further processing.

Analytical procedures

The samples were pulverized in liquid nitrogen, lyophilized, weighed and kept at −30°C for analysis. In all samples the hydroxyproline content, as a reflection of the collagen level, was measured as described previously and essentially according to the method of Prockop and Udenfriend[12]. Total protein was assayed by the Lowry method[13], using bovine serum albumin as a standard. Statistical methods employed are mentioned with the results.

Results

The hydroxyproline concentrations in uninjured intestine, as represented by the control segments removed at operation, are shown in *Table 1*. Concentrations were always higher in the colon than in the ileum. While hydroxyproline levels were significantly higher in the ileum of germ-free rats than in control rats, the colon of germ-free rats contained significantly less hydroxyproline than the colon of control rats.

Construction of an anastomosis strongly affects hydroxyproline concentrations around the operative area, both in the ileum (*Figure 1*) and in the colon (*Figure 2*). In control rats, the postoperative decrease in hydroxyproline levels was most

Table 1 *Hydroxyproline concentrations in control segments*

	Days on which rats killed	*n*	Hydroxyproline concentrations: Ileum	Hydroxyproline concentrations: Colon
Control rats	2	10	7·3 (1·7)	15·3 (2·6)
	3	10	7·5 (1·9)	16·2 (3·9)
	7	10	7·2 (1·4)	15·4 (1·8)
Total		30	7·4 (1·6)	15·7 (2·8)
Germ-free rats	2	7	9·3 (2·1)	12·9 (2·9)
	3	11	7·9 (0·9)	12·1 (1·8)
	7	7	9·3 (0·9)	15·0 (1·9)
Total		25	8·7 (1·5)	13·1 (2·5)
Control *versus* germ-free			$P=0{\cdot}0045$	$P=0{\cdot}0015$

Results are expressed as mean (s.d.) in micrograms per milligram dry weight. The levels of significance for the differences observed between germ-free and control rats are calculated by the Kruskal–Wallis K-sample test

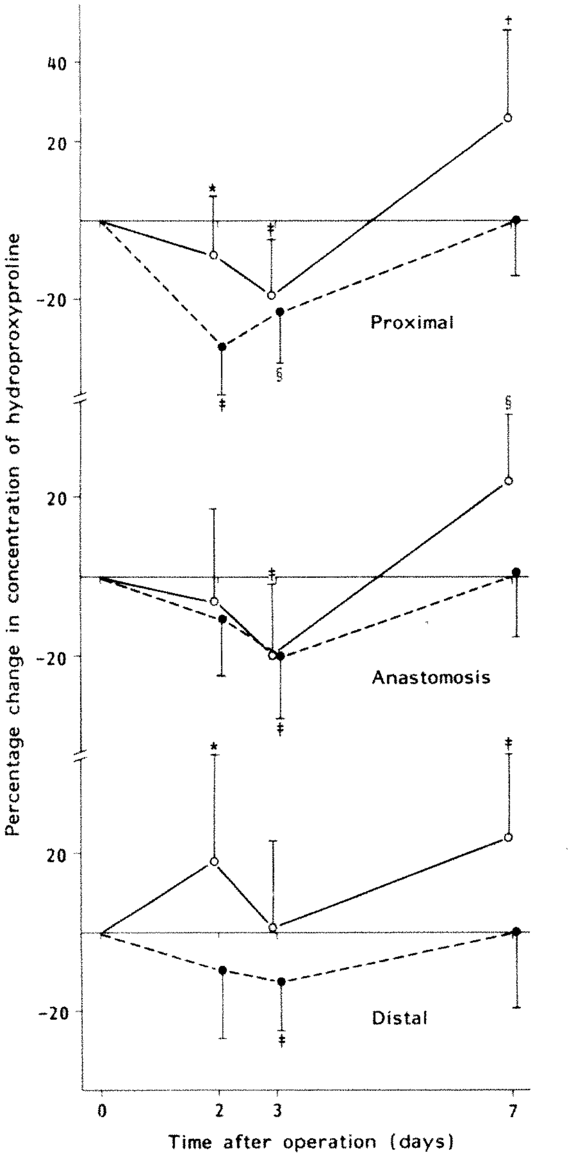

Figure 1 *Relative changes in hydroxyproline concentrations around ileal anastomoses. Results are expressed as mean percentage change, calculated with respect to the preoperative value, with standard deviation, for control (○) and germ-free (●) rats. Levels of significance for the difference between postoperative and control segments are calculated by means of a paired sample two-sided Student's* t *test and are represented as follows:* $*0{\cdot}05<P\leqslant0{\cdot}1$; $\dagger0{\cdot}01<P\leqslant0{\cdot}05$; $\ddagger0{\cdot}001<P\leqslant0{\cdot}01$; $\S P\leqslant0{\cdot}001$

pronounced in the colon; a significant difference was found between levels in uninjured colon and both the anastomosis proper and its proximal segment at all three time points. A similar phenomenon was seen in the ileum, where the effect was less marked and where preoperative levels were restored more rapidly. No lowering of hydroxyproline concentrations was seen in the area distal to the anastomosis. The transient reduction of hydroxyproline concentrations in proximal and anastomotic segments was also observed in germ-free rats. However, there were significant quantitative differences between the control and germ-free groups (*Table 2*). In the colon, the reduction of hydroxyproline levels was less marked in germ-free than in control rats, particularly in the anastomosis at 2 and 3 days and in the proximal segment at 3 days after operation. In the ileum, restoration of preoperative hydroxyproline concentrations appeared retarded in germ-free rats: at 7 days levels had only returned to preoperative values while at this time they were significantly enhanced in control rats.

As the changes in the immediate wound area are probably most relevant to the healing sequence, the apparent differences between germ-free and control rats in the anastomotic segment are of most interest. Hydroxyproline changes have been expressed in terms of concentrations (μg/mg dry weight). To determine whether the differences in postoperative hydroxy-

C, control; GF, germ-free; n.s., not significant; *subscript numbers refer to the day on which rats were killed

proline concentration changes may be attributed to differences in hydroxyproline content rather than to differences in dry weight (per centimetre of anastomotic segment), we have compared the changes in dry weight of the anastomotic segments for the ileum (*Table 3*) and the colon (*Table 4*). The weight of uninjured intestine was higher in control rats than in germ-free rats: 1 cm of ileum weighed 11·7 (3·7) mg in control rats (mean and s.d.; $n=30$) and 7·3 (2·7)mg ($n=25$) in germ-free rats ($P<0{\cdot}0001$); values for colon were 9·4 (3·0) and 7·8 (2·1)mg ($P=0{\cdot}02$), respectively. In the ileum, the weight of the anastomotic segment increased with time, while it remained constant in the colon. The increase in weight relative to that of the control segment was similar in control and germ-free rats, except in the ileum 2 days after operation. Likewise, there were no significant differences in the weight change of the proximal segment in germ-free and control rats (results not shown), except in the ileum after 2 days, where the weight gain was significant in germ-free rats.

Finally, total protein concentrations were measured in those segments where the reduction in hydroxyproline levels was most

Table 5 *Colonic protein concentrations in control and anastomotic segments 2 and 3 days after operation*

pronounced (i.e. in the colon anastomoses 2 and 3 days after operation). *Table 5* shows that there was no significant decrease in protein concentration in any of the groups investigated.

Discussion

The negative influence of micro-organisms on anastomotic healing in the large bowel has often been suggested[14–15]. Indeed, bowel preparation with antibiotics and irrigation appears to be beneficial to healing of experimental and human colonic anastomoses[16–20]. The mechanism whereby intraluminal bacteria affect wound healing remains a matter for speculation, but interference with anastomotic collagen metabolism could be involved. Therefore, it is of interest to investigate the behaviour of collagen concentrations in animals whose digestive tract is completely free from bacterial contamination. In the present study, operations on germ-free rats kept in a horizontal laminar flow workstation yielded a relatively high contamination rate (44 per cent) but provided enough uncontaminated rats for analysis.

The importance of collagen in maintaining and restoring the structural integrity of the intestinal wall seems undisputed. The concept that the 'collagenous equilibrium' is crucial for undisturbed healing is widely accepted[8]. Both collagen degradation and collagen synthesis are inherent in the healing sequence. Investigations into the healing process of intestinal anastomoses frequently comprise measurements of hydroxyproline concentration (per milligram dry weight) or hydroxyproline content (per centimetre). Neither allows quantitative conclusions regarding the separate processes of collagen degradation and synthesis, as a given level at a certain time only reflects the net result. However, the postoperative decrease in hydroxyproline concentration is taken to support the assumption that collagen degradation occurs. Comparison of the course of change in hydroxyproline concentrations during the first postoperative days in various groups of animals is meaningful if it can be shown that eventual differences are the result of changes in collagen content, rather than changes in total dry weight. Thus, if we want to compare changes in hydroxyproline concentrations around anastomoses in control and germ-free rats, it appears pertinent to show that the development of the increase in dry weight in the various segments is similar in both types of rat. This is shown in *Tables 3* and *4* for the anastomotic segment, where the events must have the most direct effect on wound strength. While the absolute weight of segments from uninjured intestine from germ-free rats was smaller than that from control rats, it can be seen that, with one exception in the ileum, the relative increase in anastomotic weight was identical in both types of rat. Therefore, differences in hydroxyproline concentrations may be attributed to differences in collagen metabolism. In control rats, the postoperative decrease in hydroxyproline concentration was most pronounced in the colonic anastomosis; total protein content did not change. In germ-free rats, reduction of hydroxyproline levels still occurred but was consistently and significantly less pronounced. The same difference between control and germ-free rats was found in the proximal segment, particularly after 3 days. These results are taken as evidence that in the colon bacteria contribute to the postoperative degradation of collagen in the anastomotic area. This seems not to be the case in the ileum. Here, the increase in hydroxyproline observed after 7 days in control rats was significantly reduced in germ-free rats. This could mean that bacteria also affect (in a negative way) collagen synthesis.

As a result of the absence of exposure to bacteria, germ-free rats differ in many respects from normal Wistar rats[21,22]. Their cardiac output is 30 per cent lower, the regional blood flow in many organs is reduced, and they do not possess a stimulated immune-response system. Differences are also found in the intestinal tract: the small intestine appears somewhat thin walled (cf. *Table 3*), the caecum is much larger and the large bowel content is more liquid than in conventional experimental rats. Despite these differences, it is our contention that our data support the hypothesis that colonic flora may be detrimental to colonic healing by affecting collagen metabolism. One result of construction of an anastomosis seems to be increased collagenolytic activity[23]. As bacteria contain collagenase activity they might directly enhance postoperative collagen breakdown[9]. Alternatively, their presence could strengthen the inflammatory response and thus the activity and enzyme production of granulocytes, which are also a rich source of collagenolytic activity[24]. Collagen synthesis by fibroblasts is also an integral part of the healing sequence. Bacteria could also interfere with anastomotic healing by parasitizing available oxygen from tissue fibroblasts and thus decreasing their synthesizing capabilities[25].

The present results allow no conclusions about which of these possibilities are correct, although the results observed in the ileum after 7 days argue against bacterial inhibition of collagen synthesis. They only support the idea that bacteria do indeed affect postoperative collagen levels in the intestinal wall. Further confirmation of their role should come from studies of the effect of bacteria on the separate processes of collagen degradation and synthesis.

Juvenile polyp in an ileoanal J pouch following restorative proctocolectomy for juvenile polyposis coli

A. Sene, P. E. Thomas, V. Gautam, N. J. Andrews, R. F. T. McMahon and T. V. Taylor

A juvenile polyp is described developing within ileal mucosa in an ileoanal J pouch 10 months after restorative proctocolectomy for severe juvenile polyposis coli. We believe that this is the first recorded case of a hamartomatous juvenile polyp arising in the mucosa of an ileal pouch.

Case report

A 16-year-old male patient was referred for definitive treatment of juvenile polyposis coli. He gave an 8-month history of intermittent rectal bleeding, prolapsing rectal polyps and profound anaemia (5 g/dl) requiring several blood transfusions. Colonoscopy revealed hundreds of polyps throughout the large bowel with prominent clusters in the rectum and caecum. His mother also had colonic polyps but these were fewer in number and almost entirely confined to the rectum. No other close relative was affected.

The patient underwent restorative proctocolectomy with formation of a J ileal pouch and ileoanal anastomosis. No polyps were seen in the 30 cm of ileum used to construct the pouch. Histopathological examination of the colon confirmed juvenile polyposis coli. The polyps were composed of oedematous chronically inflamed lamina propria covered by focally ulcerated colonic epithelium with no evidence of dysplasia or neoplasia. After closure of the covering ileostomy the pouch functioned satisfactorily 4–5 times per day with complete continence and no further bleeding.

Ten months later the patient again became anaemic, complaining of bleeding from the pouch and of a prolapsing lump obstructing defaecation until pushed aside by a finger. He required further blood transfusion. Examination under anaesthetic revealed a pedunculated polyp, 3 cm in diameter, arising from ileal mucosa and prolapsing through the anus. The stalk was transfixed and the polyp excised (*Figure 1*). Histology showed this to be another juvenile polyp covered predominantly by epithelium of small intestinal type although foci of gastric (pyloric) and colonic metaplasia were noted (*Figure 2*). There was no evidence of dysplasia or neoplasia. The patient made a satisfactory recovery but a later small bowel enema examination has demonstrated the presence of a number of polyps in the small bowel which are, as yet, asymptomatic.

Discussion

Multiple juvenile polyposis may be sporadic or inherited as an autosomal dominant. The polyps develop either in the large bowel alone or in the whole gastrointestinal tract. There is said to be a very small risk of malignancy in this condition compared with that associated with familial adenomatous polyposis[1].

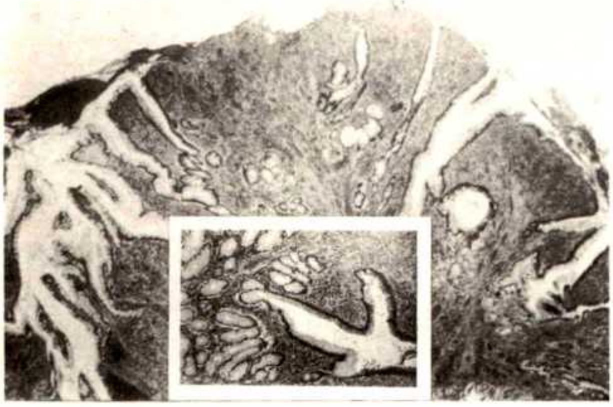

Figure 2 *Polyp from ileal pouch with prominent lamina propria showing surface ulceration. It is lined mainly by small intestinal epithelium but (inset) demonstrates foci of pyloric and colonic metaplasia. (Original magnification ×60)*

Adenomatous polyps have also been described in cases of juvenile polyposis[2,3]. If the rectum is relatively spared of polyps it is not generally necessary to perform proctocolectomy: subtotal colectomy with ileorectal anastomosis and local diathermy are usually sufficient. In the above case, however, there was severe rectal involvement, with bleeding, profound anaemia and prolapse. Serious complications of multiple juvenile polyposis necessitating urgent colectomy include intractable bleeding and severe fluid and electrolyte losses[4,5].

A juvenile polyp is a hamartomatous development of the lamina propria. In our case the polyp appeared to have developed from the pouch mucosa because its pedicle was about 5 cm long and no polyps were noted during the construction of the pouch. It is known that benign neoplasia of the small bowel occurs in patients with familial adenomatous polyposis and adenomatous lesions have been described in the Kock ileal reservoir after proctocolectomy for familial adenomatous polyposis[6,7]. The pouch polyp in our case was a juvenile polyp developing in previously normal-looking ileal mucosa lining the ileal pouch, and we believe this is the first such case on record.

This polyp showed some of the inflammatory features described in the ileal pouches of patients with ulcerative colitis and familial adenomatous polyposis; this includes colonic metaplasia, which has been suggested may predispose to later neoplasia[8]. Regular surveillance has been recommended for pouches fashioned in cases of familial adenomatous polyposis[9]. In view of our findings we would extend this recommendation to include regular surveillance of all cases with ileal reservoirs performed for polyposis whether adenomatous or otherwise.

Stepping Forward into the Future
To better Soft Tissue Repairs

The GORE-TEX® Expanded PTFE Soft Tissue Patch makes soft tissue repairs safer, easier and more effective than ever before.

It's strong enough for the repair of massive ventral hernias, but flexible enough for the more delicate reconstructions.

The Soft Tissue Patch was soon reported to be easier to handle and position – and it won't fray at the edges. Its suture retention strength is also one of the highest currently available with prosthetics materials.

The unique porous microstructure of GORE-TEX® Expanded PTFE allows the patch to be incorporated into the surrounding tissue, rather than encapsulated, and it has been shown not only to be resistant to the spread of infection, but also to be treatable if infection is present.

Six years of successful clinical use have proved it: the GORE-TEX® Soft Tissue Patch is an important step forward in soft tissue reconstructions and hernia repairs.

® GORE-TEX is a registered trade mark of W L Gore & Associates Inc.

Expanded polytetrafluoroethylene patch for the repair of large abdominal wall defects

**B. van der Lei,
R. P. Bleichrodt,
R. K. J. Simmermacher
and R. van Schilfgaarde**

Department of Surgery, University Hospital Groningen, P.O. Box 30.001, 9700 RB Groningen, The Netherlands

Correspondence to:
Mr R. P. Bleichrodt

Expanded polytetrafluoroethylene (ePTFE) was used to repair 11 large abdominal wall defects in ten patients. Three patches were fixed to the adjacent abdominal aponeurosis with a single row of sutures; seven patches were implanted with a 1–2 cm overlap of patch and aponeurosis and a double row of sutures. Recurrent buttonhole hernias were found in two patients, in both of whom a single row of sutures had been used. This reherniation was due to insufficient anchorage of the patch to the fascia. It is concluded that ePTFE is a useful material to repair large abdominal wall defects provided the patch is fixed to the aponeurosis with an overlap and a double row of sutures to prevent buttonhole hernias.

Keywords: Hernia (ventral), expanded polytetrafluoroethylene, soft tissue patch

Large abdominal wall defects resulting from trauma, necrotizing infection, tumour resection or other causes continue to be a major problem for both patients and surgeons. The lack of sufficient tissue may require the insertion of a prosthetic material. Polypropylene mesh (Marlex®, C.R. Bard Incorporated, Murray Hill, New York, USA) is still the most widely used material for this purpose. It is relatively cheap and usually suffices well, although its propensity for inducing extensive visceral adhesions and occasional fistulation is a well recognized drawback[1–5].

Recently, an expanded polytetrafluoroethylene (ePTFE) patch (GORE-TEX® Soft Tissue Patch, W.L. Gore and Associates Incorporated, Flagstaff, Arizona, USA) has been introduced. Thus far, only two reports have been published in the English literature on the clinical use of this material for the reconstruction of large abdominal wall defects, involving in all 29 patients[6,7].

The present report extends this experience with the long-term results obtained in ten patients treated in our department, illustrating two important problems that can be encountered by using this material: buttonhole hernia and erythema of the skin in combination with prolonged subfebrile temperature.

Patients and methods

Between April 1985 and August 1986, 11 abdominal wall defects in ten patients were reconstructed with ePTFE. There were four men and six women with a mean age of 47 years (range 9–72 years). In all instances, the defect was too large for primary closure and omentum was not available for interposition between viscera and patch. Four defects were associated with recurrent incisional hernia, three with open treatment of generalized peritonitis and one with tumour resection. Two defects were congenital in origin. The dimensions of the hernias varied between 5 × 10 cm and 15 × 20 cm. Two patients, who had previously been treated with Marlex mesh after open treatment of generalized peritonitis, showed persistent fistulation. The remaining operations were performed in a clean uncontaminated field.

Standard sterile surgical procedures were performed. No antibiotic prophylaxis was used. The skin was disinfected with iodine tincture. The fascial margins of the hernia were identified and, if necessary, the peritoneal cavity was explored to dissect any loops of intestine adherent to the parietal peritoneum near the fascial margin. An ePTFE patch of 2-mm thickness was tailored to the desired shape so as to cover the fascial gap without excessive tension. The patch was sutured with interrupted polypropylene 0 sutures to the fascial margin with no overlap between fascia and patch in three patients, and with a 1–2 cm overlap and a double row of sutures in all the other patients (*Figure 1*).

Postoperatively, the wounds were inspected daily during hospital stay, at intervals of 3–4 months during the first year, and at yearly intervals thereafter. No patients were lost to follow-up.

Results

The mean follow-up was 31·5 months (range 21–41 months). Early postoperative complications were subcutaneous haematoma ($n = 1$), seroma ($n = 1$), and erythema of the overlying skin combined with subfebrile temperature during the first postoperative week ($n = 2$). These complications were transient and required no surgical intervention.

Primary wound healing with an uneventful postoperative course was observed in seven patients. Postsurgical complications requiring reintervention were observed in three patients.

One of two patients with persistent fistulation after previous Marlex implantation developed a postoperative wound infection. Systemic antibiotic treatment was unsuccessful, and when the ePTFE patch was removed 1 month after operation it had completely deteriorated. It was surrounded by large amounts of purulent exudate, but a thick layer of fibrous tissue was observed under the patch. The remaining wound defect was partly closed without prosthetic material and healed well. No hernia recurred, probably because of the fibrous tissue that

had formed underneath the ePTFE patch. Cultures revealed *Staphylococcus aureus*.

Reherniation was observed in two of the three patients in whom the patch had been inserted with a single row of sutures and without overlapping the fascial margin. In both patients bowel appeared to herniate between sutures at the patch–fascia interface (i.e. buttonhole hernias). In one patient, a single buttonhole hernia of about 1 × 2cm between the patch and the fascial margin was observed 2·5 months after operation. This defect was successfully treated by placing two additional stitches between the patch and the fascia. In the other patient, four small buttonhole hernias, each of about 1 × 2 cm, were observed between the patch and the fascia 3 months after operation. In this case the patch was removed 6 months after the initial operation. There appeared to be minimal loose adhesions between the bowel and the patch. A new, larger ePTFE patch (10 × 20 cm) was implanted by means of the double row of sutures with overlap technique, and the subsequent course was uncomplicated. Histological analysis of serial sections of the removed patch showed absence of ingrowth of fibrocollagenous tissue into the patch (*Figure 2*). A similar histological pattern was seen in a second patient in whom a patch was removed during the construction of a continent urostoma, 41 months after implantation.

A good result was ultimately achieved in all instances. All patients took up their normal activities and regained a normal abdominal wall contour with no puckering and no rigidity to betray the underlying patch.

Discussion

Our report illustrates the clinical efficacy of ePTFE for the reconstruction of large abdominal wall defects. It also draws attention to two pertinent aspects that have not previously been reported: the erythema of overlying skin and the subfebrile temperature which may transiently occur soon after operation; and the importance of using the double row of sutures with overlap technique (*Figure 1*) to prevent recurrence of buttonhole hernias.

Recent experimental[8,9] and clinical[6,7] data strongly suggest that ePTFE closely meets the ideal prosthetic material to repair abdominal wall defects. Our present study corroborates these findings as we, like Bauer *et al.*[7], observed no gross interference of the ePTFE patches with wound healing, no fistulation and no intestinal obstruction. Moreover, at explantation of two patches we found only minimal loose adhesions to the bowel and a low-grade inflammatory reaction around the patches.

Unlike others, however, we observed a rather conspicuous reaction after implantation of an ePTFE patch; this occurred in two patients, who showed erythema and prolonged subfebrile temperature in the postoperative period. The clinical importance of this phenomenon lies in the fact that it should not be confused with signs of infection.

The present study seems to advocate the use of the double row of sutures with overlap technique (*Figure 1*) for the implantation of ePTFE patch to prevent recurrence of hernias. Although our series of patients is small, we observed recurrence of hernias only in those patients in whom no double row of sutures and overlap had been used (two of the three patients). Recurrence of these hernias (all occurred within the first few months) was observed at re-exploration to be due to herniation of bowel between sutures at the patch–fascia interface (i e. buttonhole hernias). Moreover, histological analysis of two patches at 6 and 41 months after the original operation revealed poor anchorage of fibrocollagenous tissue to the patch: the fibrocollagenous tissue was separated from the patch by a zone of macrophages (*Figure 2*). Also, the internodal space of the ePTFE patches (fibril length 10–20 μm) is too small to allow good ingrowth of fibrocollagenous tissue. Even PTFE material with a fibril length of 30 μm permits little tissue ingrowth[10]. This actually indicates that anchorage at the patch–fascia interface depends mainly on the suture technique at the patch–fascia interface. This idea is supported by an observation of Bauer *et al.*[7] who at exploration of a buttonhole hernia in a patient found a single polypropylene suture untied and free at the ePTFE patch–fascia interface. It seems that the double row of sutures with overlap technique (*Figure 1*) is a method that eliminates the risk of reherniation of bowel at the patch–fascia interface.

Infection occurred in one patient (one of the two patients who had a contaminated operation field). Although ePTFE is less adherent for bacteria compared with polypropylene mesh[11], its use in contaminated wound areas should be avoided. Recent experimental studies in our laboratory revealed that ePTFE, when used to reconstruct contaminated abdominal wall defects, showed a significantly higher incidence of infection and patch extrusion compared with polypropylene mesh[12]. Additional coating of an ePTFE patch with antibiotics may improve its resistance to infections, as has already been demonstrated for ePTFE arterial prostheses[13], and may broaden the indication for its clinical use.

In conclusion, the present study underlines the clinical usefulness of ePTFE material for the reconstruction of large abdominal wall defects. Because of the costs of this material, and the result with Marlex, we reserve this material for patients in whom the underlying peritoneum cannot be re-established and in whom there is insufficient omentum. The patch should be implanted with a 1–2 cm overlap between fascia and patch and a double row of sutures to prevent recurrence of buttonhole hernias. Erythema and prolonged subfebrile temperature may be observed in some patients. More clinical data should determine the ultimate place and indication for the ePTFE patch.

Mr R. J. Nicholls

Two hundred and twenty-eight patients with anal carcinoma treated between 1948 and 1984 were reviewed. Of 145 with anal canal carcinoma, 118 were treated by total anorectal excision, nine by local excision and 13 by radiotherapy. Fifteen patients were inoperable. There were five postoperative deaths. Crude and cancer-specific survival rates of 123 patients treated 5 or more years previously were 58 and 64 per cent. These rates for patients undergoing total anorectal excision were 62 and 65 per cent, and local excision 87 and 100 per cent. Eighty-three patients had carcinoma of the anal margin. Of these, 55 were treated by local excision, 18 by total anorectal excision and 20 by radiotherapy. Eight patients were inoperable. Crude and cancer-specific survival rates for 72 patients followed for 5 years were 55 and 57 per cent with respective rates of 65 and 69 per cent after local excision and 36 and 40 per cent after total anorectal excision. The 5-year survival rate of 27 patients with TNM N_1 stage was 48 per cent. Histological confirmation was obtained in only nine of these patients, however, but five (55 per cent) survived 5 years after block dissection or radiotherapy. Metachronous lymphadenopathy occurred in 25 patients. The 5-year survival rate in the 23 cases that were histologically confirmed was 35 per cent after block dissection (17 cases) and radiotherapy (four cases). Using a modification of Papillon's T classification for anal canal carcinoma, stage correlated with survival after combining T_1 with T_2 tumours and T_2 with T_3 tumours. Five-year survival rates in these groups were 60 and 54 per cent respectively. The TNM–UICC classification for anal margin carcinoma correlated with survival in a similar manner. The 5-year survival rate was 65 per cent for patients with T_1 and T_2 tumours and 33 per cent for those with T_3 and T_4 tumours.

Keywords: Anal cancer, surgical treatment, staging

There has been renewed interest in squamous cell carcinoma of the anus owing to the increasing use of radiotherapy and chemotherapy as treatment[1–13]. Although the incidence of the disease in England and Wales has been stable over the last 10 years, it is quite possible that there will be an increase in the future, given the rise in prevalence of human papilloma virus-related disease[14]. Anal cancer is, however, uncommon and few large series have been reported[5,12,13,15–18]. Some may not be comparable owing to confusion in the definition of anal margin and anal canal carcinoma and also to the inclusion of other types of anal cancer. Comparison of one study with another is also made difficult by differences in local staging systems which include those defined by the UICC (International Union against Cancer), Papillon and the Mayo Clinic[17] (*Table 1*). The last of these does not appear to have been adopted widely. The UICC classification is probably the most frequently applied but there has been no published attempt to validate it by comparing T stage with the clinical outcome.

With these considerations in mind, we set out to review the results of treatment of squamous cell carcinoma of the anus at one hospital. As a predominantly surgical series involving few surgeons, relatively large numbers of patients and a high rate of follow-up, it should provide useful up-to-date information on the results of surgery with which other treatments might be compared.

The last report from this hospital in 1968[19] included all cases treated from 1928 up to that time. In the present study, however, it was decided only to include patients who had been treated since 1948. By then the operability rate had risen to a stable figure of about 90 per cent. Thus the patients included were managed by a similar strategy based on the optimal use of surgery, with radiotherapy being used in a minority.

We also attempted to relate local features of the tumour, determined by clinical examination, to survival. Sufficient clinical information was available to enable the classification of Papillon to be applied to tumours of the anal canal and the TNM–UICC classification to those of the anal margin (*Table 1*).

Table 1 *Carcinoma of the anus: definition of T stage*

T stage	Anal canal (Papillon, 1982) modified	Anal margin (TNM—UICC, 1978)
T_1	<2 cm	T_1 <2 cm
T_2	2 cm to ≤5 cm	T_2 2 cm to ≤5 cm
T_3	>5 cm	T_3 >5 cm
T_{4a}	Invading vaginal mucosa	T_4 Extension to muscle, bone etc.
T_{4b}	Invading neighbouring structures other than skin, rectum or vagina	
T_x	Insufficient information available

Patients and methods

Between 1948 and 1984, 238 patients with squamous cell carcinoma of the anus were seen at the hospital. The case notes of all were studied and ten (4 per cent) were excluded, six because of the presence of synchronous or metachronous colorectal cancer, two in which the squamous cell carcinoma appeared to have arisen in the rectum and two with coincident Crohn's disease. Squamous cell carcinoma of the anus was defined according to the International Histological Classification of Tumours[18] and cases were divided into those occurring in the anal canal or at the anal margin on the criteria of Morson[20]. Anal canal tumours included those lying entirely above, mainly above or astride the dentate line. Tumours lying mainly below or entirely below this level were regarded to be arising at the anal margin.

Clinical staging

Local features of the tumour as recorded at the initial clinical examination were extracted from the case notes wherever this information was available. They included details of the longitudinal diameter, quadrant(s) involved, relationship to the dentate line and degree of local penetration (whether invading the internal sphincter, external sphincter or penetrating the external sphincter to invade other structures).

Anal canal carcinoma was classified using the staging system of Papillon modified to define stage T_2 as tumours from 2 to $\leqslant 5$ cm in diameter (not 2–4 cm as proposed by Papillon) and T_3 as tumours >5 cm in diameter. Anal margin carcinoma was classified using the TNM–UICC system without any modification[21,22] (*Table 1*).

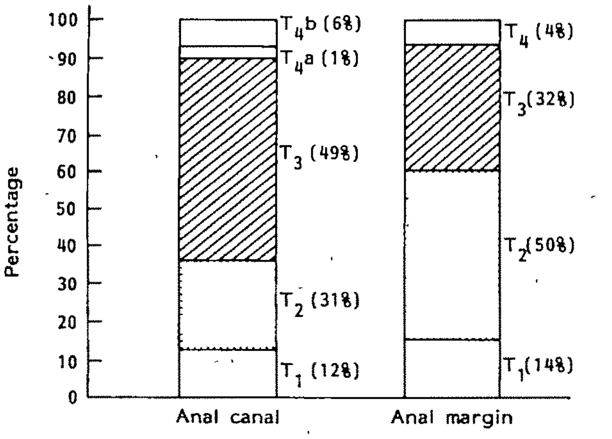

Figure 1 *Relative proportion of T stage at presentation of carcinoma of the anal canal and anal margin*

Table 2 *Anal canal carcinoma: type of treatment in 145 patients*

	No. of patients (%)	Radiotherapy (%)
Diagnosis only	3 (2)	0
Inoperable	15 (10)	13
Total anorectal excision	118 (81)*	9
Local excision	9 (6)	0
Total	145	22 (15)

* Includes five postoperative deaths

Sufficient information from the clinical notes was available to enable a T stage value to be given to 203 (89 per cent) of 228 cases, including 134 (92 per cent) of 145 patients with anal canal carcinoma and 69 (83 per cent) of 83 with anal margin carcinoma. Five-year survival rates were determined for each T stage in both the anal margin and anal canal carcinoma groups. Crude 5-year survival and cancer-specific 5-year survival rates were calculated. Survival rates were compared using the log rank test.

For the analysis of inguinal lymph node status, patients with anal canal and anal margin carcinoma were combined. The occurrence of synchronous or metachronous nodal involvement was determined from the notes. Details regarding histological confirmation, treatment and survival were recorded.

Results

There were 145 cases of anal canal and 83 cases of anal margin carcinoma.

Anal canal carcinoma

Of 145 patients, 65 were men and 80 women (male:female ratio 1:1·2). The median age at presentation was 58·7 years (range 28–87 years). The mean duration of symptoms was 10 6 months; patients with the disease most commonly presented with bleeding, pain or a lump in the anus. The distribution of T stage at presentation is shown in *Figure 1*. About half the cases were classified as stage T_3. Disseminated disease (M_1) was demonstrated at presentation in nine patients. Of 15 (10 per cent) patients considered inoperable, 13 were treated by radiotherapy (*Table 2*). The majority, 118 (81 per cent), underwent a total anorectal excision and only nine (6 per cent) were treated by local excision. Five (4 per cent) patients died in the postoperative period after total anorectal excision.

Eight (6 per cent) patients were treated less than 5 years before this study, five of the remaining 137 patients died postoperatively and five were not treated, leaving 127 patients eligible for 5-year assessment. Four of these were lost to follow-up; thus 123 patients were available for assessment of outcome at 5 years. The crude 5-year survival rate was 58 per cent (*Table 3*). Of the eight cases treated by local excision, crude and cancer-specific 5-year survival rates were 87 per cent and 100 per cent respectively. Three of the 13 patients considered inoperable who were treated by radiotherapy survived 5 years. Crude and cancer-specific 5-year survival rates after anorectal excision alone were 62 per cent and 65 per cent respectively for all cases and 71 per cent and 76 per cent for those without dissemination at the time of surgery.

Cumulative survival rates after treatment of anal canal carcinoma according to T stage are shown in *Figure 2*. There is a clear separation between T_1 and T_4 but a considerable overlap of T_2 and T_3 stages. The 5-year survival rates for patients with T_1 and T_2 tumours combined *versus* T_3 and T_4 combined of 60 per cent and 54 per cent respectively significantly different ($P>0{\cdot}05$).

Table 3 *Anal canal carcinoma: 5-year survival excluding operative deaths in 123 patients*

	All cases	Alive at 5 years	Cancer-specific survival	Curative cases	Alive at 5 years	Cancer-specific survival

Total anorectal excision + radiotherapy	8	4 (50)	(67)			
Total	123	72 (58)	(64)			

Values in parentheses are percentages

Anal margin carcinoma

Of 83 patients, 57 were men and 26 women (male:female ratio 2·2:1). The mean age at presentation was 60·7 years (range 25–89 years): the average length of history was 9·2 months (range 0–65 months) and the nature and frequency of symptoms were similar to those of anal canal carcinoma. It was possible to assign a T stage to 69 (84 per cent) of 83 cases (*Figure 1*). The majority of lesions were early (T_1 and T_2, 64 per cent) and the incidence of more advanced lesions was less than that found in the anal canal (T_3 and T_4 in the anal margin, 36 per cent; T_3 and T_4 in the anal canal, 56 per cent). Four patients had demonstrably disseminated disease at presentation (M_1).

Two were seen for diagnosis only and one of the inoperable cases did not receive any radiotherapy (*Table 4*). The majority of the remainder underwent local excision (55 cases, 66 per cent). Radiotherapy was used in seven inoperable patients, in eight patients treated by local excision and in five of the 18 cases undergoing total anorectal excision. There were no postoperative deaths.

Crude and cancer-specific 5-year survival rates after excluding the two cases seen for diagnosis, the one inoperable case not treated and eight patients lost to follow-up are shown in *Table 5*. The results were very similar to those seen for anal canal carcinoma. Only one out of seven inoperable patients survived for more than 5 years after radiotherapy. Cumulative survival after treatment of growths according to T stage is shown in *Figure 3*. A similar pattern to that found in anal canal carcinoma was seen with survival of T_1 and T_2 combined (65 per cent), being significantly greater than that of T_3 and T_4 combined (33 per cent; $P<0·01$). There was no difference in the cumulative crude survival of anal canal and anal margin carcinoma (*Figure 4*).

Inguinal lymph node involvement

Twenty-seven (11 per cent) of the 228 patients were considered to have clinically involved inguinal nodes at presentation; biopsy was performed in 18 (67 per cent) cases and in only nine was tumour proved. Crude 5-year survival in the clinical N_1 group was 48 per cent and five (55 per cent) of the nine histologically confirmed cases were alive (*Table 6*). A further 25 (12 per cent) patients developed metachronous inguinal nodal enlargement; all were biopsied, and in 23 cases recurrence was confirmed. Nine (36 per cent) of these patients survived 5 years; block dissection was the commonest salvage treatment (17 cases), yielding a 41 per cent 5-year survival rate.

Discussion

The present study is one of three large surgical series[12,13,23]. Anal margin and canal lesions have been separated by Morson's criterion of the relationship to the dentate line[20]. (Others draw the dividing line at the anal verge[17]). The 93 per cent follow-up rate at 5 years is high and information on treatment and histopathology have been well documented. The series encompassed the period from 1948 to 1984 when surgery was the treatment of choice and during which resectability had achieved a maximal figure. Treatment-related mortality was confined to five (4 per cent) cases among the 136 patients undergoing major surgery. Five-year survival in those with anal canal carcinoma appeared better than for anal margin lesions with respective rates for all cases of 58 per cent and 55 per cent and cancer-specific survival rates of 64 per cent and 57 per cent. There was a significant difference in survival of combined T_1 and T_2 lesions compared with T_3 and T_4 combined. Local recurrence figures are unfortunately not available for all patients but survival to 5 years is likely to imply absence of local recurrence.

The other large surgical series have obtained similar results. For example, at Memorial Hospital, New York, USA, a 5-year survival rate of 55 per cent after total anorectal excision for anal canal carcinoma was reported. Survival depended on the size of tumour, whether <2 cm (75 per cent) or >2 cm (40 per cent) in diameter. Of the 144 cases in the series only 11 (8 per cent) were treated by local excision and of these five survived 5 years[13,23]. Similarly in the present series only eight (6 per cent) of 145 cases of anal canal carcinoma underwent local excision but seven were alive 5 years later.

In a series of 128 patients with anal canal growths external irradiation using telecobalt produced survival rates of 68 per cent for those with stage T_2 or less and 32 per cent for those with stage T_3 or over[24]. Eschwege *et al.* reported very similar respective survival rates in 106 cases of 62 and 26 per cent with 42 per cent overall survival[25]. In both these series doses of 45–65 Gy were used according to a standard protocol. Many other radiotherapeutic series have not had either such large numbers or such a defined protocol For example, the treatment given to 51 patients at Princess Margaret Hospital, Toronto, Canada included various combinations of external beam and interstitial radiotherapy, although most received 45–50 Gy over 4–5 weeks[8]. The overall survival rate was 59 per cent at 5 years with local control achieved in 29 of 51 (57 per cent) patients. This survival rate, which is somewhat higher than in the series above, may be due to differences in the distribution of local stage within the groups but it is no greater than survival rates after surgery alone as reported by Greenall *et al.*[23] or in the present study.

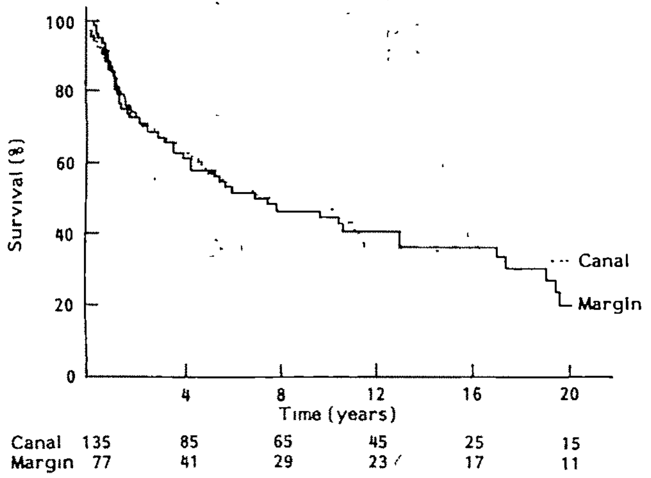

Figure 4 *Cumulative crude 5-year survival of all treated cases of anal canal and anal margin carcinoma (212 patients). The numbers of patients at risk are shown*

Interstitial radiotherapy used in 74 patients with carcinoma of the anal canal and anal margin produced cancer-specific survival at 5 years in 35 cases (51 per cent of 68 evaluable patients) There was, however, a need for salvage surgery in six patients for radionecrosis and 26 for recurrence. Survival was related to the initial size of the tumour (64 per cent, tumour <5 cm: 23 per cent, tumour >5 cm)[26].

Papillon has maintained that results of external beam radiotherapy can be improved by a split course of treatment[5,27]. This includes an initial irradiation by external beam to a dose of 30 Gy followed after an interval of 1·8 weeks by an interstitial implant of iridium for 24 h, adding a further 10–15 Gy. In a series of 158 patients with anal canal carcinoma followed for 5 years, only 20 per cent died of cancer and the overall crude disease-free survival rate was 65 per cent[5]. He pointed out that not all patients having radiotherapy avoided a colostomy but reported that 67 per cent of those with a T_3 stage tumour or less and 52 per cent with a T_4 stage tumour were alive and without a stoma at 5 years. These results certainly compare very well with those after major surgery and against other radiotherapy regimens. However, when comparing the overall results of surgery and radiotherapy, there is every indication that the former is as effective or more so than the latter in terms of survival and, as would be expected, the efficacy of each is related to local stage.

There has not been a satisfactory trial of combined radiotherapy and surgery for anal carcinoma This is due to the rarity of the disease, which has discouraged establishment of treatment protocols, and the introduction of multidisciplinary combined treatment developed by Nigro *et al.*[1,34]. In 31 patients initially treated by radiotherapy (30 Gy) and chemotherapy (5-fluorouracil and mitomycin C) followed by anorectal excision, no tumour was found in the operative specimen in 22 (71 per cent). As a result patients have subsequently been submitted to examination under anaesthesia with biopsy of the tumour site only after the initial treatment. In only one of 61 patients so treated was the biopsy positive and only seven cases have developed a late recurrence (treated by total anorectal excision). Of 20 deaths occurring in 104 patients, 13 have been due to recurrence[4]. These encouraging results

Table 6 *Clinical inguinal lymph node involvement in 228 patients*

		Histological status			Treatment (pathology positive)		
	No of patients	No histology obtained	Histology negative	Histology positive	Block dissection	Biopsy only	Radiotherapy
Synchronous							
Total no of patients	27	9	9	9	4	1	4
Alive at 5 years	13 (48)	4 (44)	4 (44)	5 (55)	3	—	2
Metachronous							
Total no. of patients	25	0	2	23	17	2	4
Alive at 5 years	9 (36)	—	1	8 (35)	7	1	1

Values in parentheses are percentages

have led others to adopt this treatment but the 5-year survival rates of adequate numbers of cases prospectively staged before treatment are not yet known. Randomized controlled trials of this treatment regimen are required and the results of the present surgical study should be useful for comparison because they represent the application of surgery to its maximal capacity.

Clinical staging

The TNM–UICC classification[22] applied to anal canal carcinoma includes four stages (T_{1-4}) based on the degree of penetration of the sphincter muscles and structures beyond. Such assessment is clearly a difficult exercise for the clinician and there are no data supporting its validity. Indeed the only study available has shown no relationship between survival and UICC T stage[8]. Most other clinical staging systems for anal canal carcinoma have not been generally accepted[17,28,29] but the simplicity of Papillon's classification based mainly on the diameter of the tumour should be readily applicable. In his own series of 66 patients followed for 5 years, Papillon reported survival rates of 76 per cent for T_1 and T_2 tumours and 61 per cent for T_3 tumours with local failure rates of 10·2 per cent and 24 per cent respectively. We have also been able to show a similar relationship between a slightly modified Papillon T stage in survival in the present study, discrimination being greatest between T_1 and T_4 tumours and for T_1 and T_2 combined, on the one hand, and T_3 and T_4 combined, on the other. The TNM–UICC system applied to anal margin carcinoma in the present series was also related to survival but again only when stages T_1 and T_2 and stages T_3 and T_4 were combined. Thus a separation of tumours into those >5 cm and those $\leqslant 5$ cm in diameter appears to be a useful indicator of prognosis and is also simple to apply. In neither anal canal nor anal margin carcinoma was there any significant survival difference between T_2 and T_3 lesions.

From the results of this study and that of Papillon, it seems justified to suggest that anal canal and anal margin carcinoma can each be divided into two clinical groups, i.e. tumours >5 cm or $\leqslant 5$ cm in diameter.

Inguinal lymph nodes

Clinical inguinal lymph node involvement was found to correspond with the presence of metastatic tumour in only half the cases biopsied. This suggests that enlarged nodes may often be due to chronic infection in the primary tumour. Previous reports have drawn attention to the difference in survival rates of patients with synchronous and metachronous metastases. For example, Greenall *et al.*[13] reported 5-year survival rates of 13 per cent and 69 per cent in groups of 11 and 16 patients respectively. In an earlier study from St. Mark's Hospital, Wolfe and Bussey reported crude 5-year survival rates of 21·3 per cent for synchronous and 45·5 per cent for metachronous lymphadenopathy[15]. In the present study, however, this difference was not found. Although the total number of cases with histologically proved synchronous inguinal metastases was small (nine patients), five survived after treatment for 5 years. Perhaps this difference can be accounted for by different proportions of fixed advanced lymphadenopathy in the various series but clinical information is not available to determine this point. It may be, however, that a policy of initial biopsy of an enlarged node allows patients with early metastatic disease to be identified before their presentation with metachronous lymphadenopathy such that immediate treatment improves prognosis.

Management of thyroglossal cysts in children

A. C. Athow, N. L. K. Fagg* and D. P. Drake

*Departments of Paediatric Surgery and *Histopathology, United Medical and Dental School, Guy's Hospital, St. Thomas St, London SE1 9RT, UK*

Correspondence to: Mr D. P. Drake, The Hospitals for Sick Children, Great Ormond Street, London WC1 N3JH, UK

Forty children with a suspected thyroglossal cyst were operated on by one paediatric surgeon receiving primary and secondary referrals in an 8-year period. Nine patients (22 per cent) proved to have other pathology. Multiple operations were required in eight of 17 patients (47 per cent) who had infected thyroglossal cysts but in only one of 14 (7 per cent) with uninfected cysts. In the infected group preliminary incision and drainage was necessary in five cases and cyst recurrence occurred in four (24 per cent), whereas in the uninfected group there was only one recurrence (7 per cent) in a patient with double pathology. Infection and recurrent cysts were the chief reasons for multiple operations. Recurrence was caused by inadequate performance of the correct operation (Sistrunk's) or choice of the wrong operation. Two of our own three recurrences were due to the latter, other pathology being suspected intraoperatively. Histological study of the specimens showed that thyroglossal ducts were frequently multiple and widely spaced. In children any lesion whose presentation is typical of a thyroglossal cyst should be treated with an early Sistrunk's operation. The operation in children who have other pathology has no complications and is justified.

Keywords: Thyroglossal remnants, child

Thyroglossal cysts are the commonest cause of midline neck swellings between the ages of 6 months and 15 years[1]. The surgeon's main aim is to perform one adequate operation and avoid recurrence, which is said to be commoner in children than in adults[2].

The majority of thyroglossal cysts lie close to the hyoid bone, though they may be at any site along the pathway of descent of the thyroid anlage The hyoid fuses anteriorly in the sixth gestational week and may include remnants of the thyroglossal duct[1,3].

Howard and Lund[4] have recently emphasized the importance of adequate neck dissection for thyroglossal remnants, in order to avoid an incomplete operation. Excision of the central portion of the hyoid bone and dissection of the thyroglossal duct was first described by Shlange[5] in 1893. Sistrunk[6] popularized the operation in 1920, advising excision of a quarter of an inch (0·63 cm) of mid-hyoid bone and a cuff of muscle an eighth of an inch (0·32 cm) wide around the duct to prevent it fragmenting before the back of the tongue was reached. Attention has been drawn to the fact that the duct is frequently multiple and branched[7,8]. Mickel and Calcaterra[9] even proposed modifying Sistrunk's operation to involve a wider anterior neck dissection in adults, removing 3–4 cm of central hyoid bone and a 2–3 cm core of muscle up to the foramen caecum.

Infection is a second factor predisposing to multiple operations[10].

Patients and methods

The case notes were reviewed of all children with a midline cervical swelling presenting to one paediatric surgeon from January 1980 to December 1987. Thirty-seven patients were primary referrals and three were secondary referrals having had previous surgery.

The following information was recorded: sex, age at presentation, length of history, mode of presentation, preoperative investigations, operations performed and operative findings, histology of the lesion, postoperative complications, length of follow-up, and final outcome.

It was not our policy to carry out radioactive iodine isotope scans routinely.

The routine histological sections consisting of representative samples from each specimen were reviewed. The criteria for diagnosis were the presence of ductular or cystic structures lined by simple cuboidal or columnar epithelium, or non-keratinizing stratified epithelium without the epidermal appendages Additional findings recorded were the presence of associated minor mucous glands, lymphoid elements and thyroid acini.

Results

There were 40 children whose ages at presentation ranged from newborn to 11 years with a mean age of 3·8 years. Of the 31 children with thyroglossal cysts, there were 15 boys and 16 girls. The nine with other pathology included seven girls and two boys.

The length of follow-up ranged from 4 months to 6 years 6 months, with a mean of 2 years 8 months. There was one postoperative wound infection with *Staphylococcus aureus*

Children with infected thyroglossal cysts

An infected thyroglossal cyst (*Table 1*) was present in 17 children. The mean length of history was 5·4 months. All the lesions were in the midline except one, which was a discharging sinus to the left of the midline.

Seven were enlarging or erythematous neck swellings, three were abscesses, and seven were discharging sinuses of which four were spontaneous and three postoperative.

Five of these children had had an upper respiratory infection shortly before presentation.

Multiple operations were carried out in eight of these patients (47 per cent); five children had two operations, two had three operations and one required four operations. Incision and drainage was necessary before definitive surgery in five patients. Recurrence occurred in four children: two referred from elsewhere and two of our own. One of our recurrences followed a simple excision, when the lesion at operation appeared not to be a thyroglossal cyst, and three recurrences followed definitive surgery.

Children with uninfected thyroglossal cysts

Fourteen children presented with uninfected thyroglossal cysts (*Table 2*). None had had a recent respiratory tract infection. The mean length of history was 7·5 months.

Thirteen children had a Sistrunk's operation initially. One

S, Sistrunk's operation, TGC, thyroglossal cyst, E, excision; D, dermoid cyst

(No. 30) was a 4-year-old girl with double pathology: a ruptured dermoid cyst and a thyroglossal cyst.

The only recurrence was in a patient (No. 22) who did not have a Sistrunk's operation initially, but had a simple excision twice for an apparent dermoid cyst Only after a Sistrunk's operation on the third occasion was it demonstrated that a thyroglossal remnant and a dermoid cyst were both present.

Patients presenting at birth with midline cervical pathology

Patient No. 22 had a 1-cm fluctuant swelling operated on at 6 weeks of age. No. 17 discharged milky fluid intermittently from a submental sinus when feeding, and at 10 months presented with an infected swelling. A sinogram showed a cyst at the base of the tongue communicating with a second cyst adjacent to the hyoid bone, which proved to be thyroglossal remnants after Sistrunk's operation. A patient aged 2 years had a dermoid cyst, and No. 19, aged 9 years, had a thyroglossal cyst removed at Sistrunk's operation.

Histopathology

In 28 cases evidence of a thyroglossal remnant was present. In six of these, inflammation was heavy though some thyroglossal elements were recognizable. In three cases, chronic inflammation obscured any pre-existing structures and so the diagnosis of thyroglossal remnant could not be made (*Table 1*: designated as infected). In two, both a thyroglossal remnant and a dermoid cyst were present.

In the cases diagnosed as thyroglossal cysts by the criteria previously described, the number of epithelial lined structures varied from a solitary cyst up to one with 20 separate ductules, which were found in groups often widely dispersed along the hyoid bone and in the surrounding striated muscle (*Figure 1*). Most of the specimens showed multiple ducts. In the three cases that recurred after Sistrunk's operation, the number of ducts present were 1, 15 and 20 respectively, which was a similar range to that seen in the non-recurrent group. The mean length of hyoid resected was 15 mm. Associated minor mucus glands were present in 18 out of 28 cases and were numerous in seven. Thyroid tissue was present in ten cases.

Patients with other pathology

Histology and microbiology of the remainder revealed five dermoid cysts, one fibromatosis and three lymph nodes, one a case of chronic lymphadenitis from which *Mycobacterium avium*

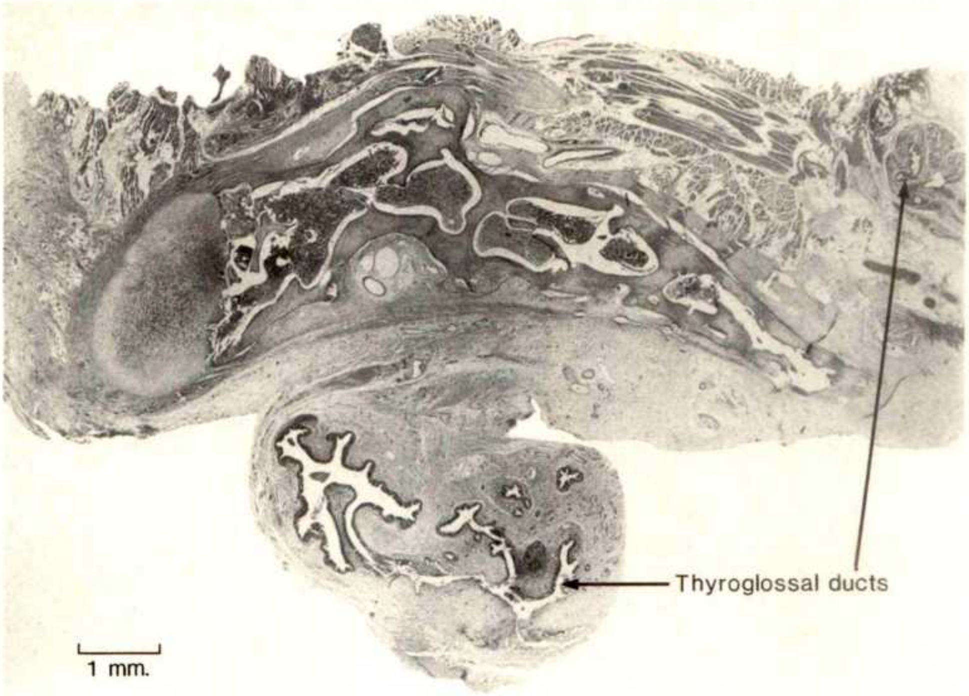

Figure 1 *Excised segment of hyoid bone with thyroglossal duct remnants close to resection margin; magnification × 15*

intracellulare scrofulaceum (MAIS) was cultured. Seven had a Sistrunk's operation and two had simple excision.

Discussion

It is of value to present the group of 40 children as a whole because the nine with diagnoses other than thyroglossal cysts were indistinguishable preoperatively and sometimes peroperatively. In a large paediatric series, 31 per cent had other pathologies[8], which required surgery. Dermoid cysts are the second most common cause of midline neck swellings in children[1] and should be excised because they can become infected. The fibromatosis required complete excision and the recommended treatment for a node infected with atypical MAIS[11] is also removal.

Preoperative diagnostic difficulty occurred when the swelling was off the midline. In this series two out of 31 cysts (6 per cent) were off the midline, both to the left of the midline; this was similar to the findings in other series[12]. In a 1-year-old child the lump was initially so hard that the child was investigated for a malignant tumour. The second child, aged 9 years, had a spontaneously discharging sinus which had been present for 2 years.

In the girl with the MAIS-infected node, its cystic nature and midline position at the level of the hyoid mimicked a thyroglossal cyst. Movement of the lump on tongue protrusion can be an unreliable sign, especially in the newborn and infants, although dermoid cysts are said not to move on tongue protrusion[1].

In this series two of four children noted to have midline neck swellings at birth had dermoid cysts present, and three had a thyroglossal cyst present, one having double pathology. At this age other diagnoses must be considered, such as cystic hygroma, cavernous haemangioma, teratoma, thyroid hyperplasia and ectoptic thyroid tissue.

The two reasons for multiple operations were infection and inadequate surgery, either the correct operation inadequately performed or the wrong operation being chosen. Infection was associated with multiple operations because of the need for an initial incision and drainage procedure. Often these children have an upper respiratory tract infection in the 2 weeks before the cyst becomes inflamed and symptomatic. One girl required two drainage procedures in 2 months because the opportunity was missed to operate as soon as she became infection-free after the first operation. Also, infection contributes to recurrence by making the tract difficult to locate and by obscuring anatomical landmarks[10].

This was a factor in patient No. 11 who had a discharging sinus and was our one recurrence after 31 Sistrunk's operations (3 per cent). Another factor was our approach to the cyst, which was situated at the level of the thyroid cartilage. A low cervical incision made dissection to the back of the tongue difficult. It would have been easier to trace the tract through two incisions, one over the cyst and one over the hyoid[12].

The two other recurrences in our hands were caused by choosing simple excision to remove a lesion which appeared not to be a thyroglossal cyst at operation. Our overall recurrence rate for thyroglossal remnants was therefore three in 31 children (10 per cent). It needs to be emphasized that the surgeon should avoid a simple excision when the original presentation of the condition is typical for thyroglossal cyst, whatever the appearances at operation. We recommend a Sistrunk's operation for the majority of patients who have other pathology as there were no complications in these patients.

In the three children initially operated on elsewhere, inadequate excision was the cause of recurrence. In one (No. 13) no attempt at excision was made, in the second (No. 14) the mid-hyoid bone had not been excised, and in the third (No. 6) the tract was not traced to the root of the tongue. There is no question that Sistrunk's operation is the treatment of choice for thyroglossal cyst[13].

Histopathological examination revealed that multiple ducts can be widely spaced. We have assumed that 15 mm of central hyoid bone is adequate, although *Figure 1* shows how close excision margins may be to multiple ducts.

Successful surgical mangement of thyroglossal cysts in children requires intervention as soon as possible after presentation to avoid infection. If there is doubt about the diagnosis, the authors recommend a radical Sistrunk's operation in the first instance, as the thyroglossal tract is not always visible to the naked eye, the tract is often multiple, and there may be double pathology.

Use of an embolectomy catheter to remove a submandibular duct stone

N. P. Briffa and K. G. Callum*

Manchester Royal Infirmary, Manchester and
**Derby City Hospital, Derby, UK*
Correspondence to: Mr N. P. Briffa, Department of Cardiothoracic Surgery, Manchester Royal Infirmary, Oxford Road, Manchester M13 9WL, UK

Traditionally, stones in the submandibular duct have been removed transorally if the stone is anterior to the posterior border of the mylohyoid muscle. If the stone is posterior and therefore impalpable, most texts recommend excision of the gland[1,2]. In most cases of duct stones, removal of the gland is not necessary as 75 per cent of glands function normally when a stone has been removed[3]. When removing stones transorally, it is important to insert a stay suture behind the stone before any manoeuvre is carried out, to prevent displacement into the gland. We describe a method for recovering such stones.

Patients and methods

A 26-year-old woman presented with a 4-month history of recurrent swelling in the left submandibular region after meals. On examination there was a stone palpable intraorally, and a sialogram confirmed the presence of the stone in the intraoral part of the duct. Although palpable preoperatively, the stone proved difficult to feel at operation under general anaesthesia. A stay suture was inserted behind the probable location of the stone. The duct was probed and an incision was made on to the probe. After a thorough exploration and examination, it was concluded that the stone had slipped back. A size 2 embolectomy catheter was inserted into the duct and passed posteriorly. The balloon was inflated, the catheter was slowly withdrawn and a 2-mm stone was recovered. Following the operation, the patient was asymptomatic.

Discussion

Balloon catheters have been used for a variety of reasons such as the removal of bile duct stones[4], removal of tracheobronchial or oesophageal foreign bodies[5], and to stem bleeding from an endobronchial biopsy site[6], but this is the first report of the use of the balloon catheter to recover salivary duct stones. We present this as a useful method for removing stones that migrate during attempted transoral removal or for small stones that lie posteriorly, in order to avoid the need for gland excision.

Nine children presented with intussusception lasting for 14 days or more. Their mean age was 8·5 years. Diagnosis of intussusception was delayed considerably, probably due to an unusual presentation. Compared with acute intussusception, symptoms consist of infrequent attacks of abdominal pain, sporadic vomiting and no, or small, changes in defecation. Marked weight loss and an abdominal mass assume diagnostic significance, in contradiction to bloody stools. Ultrasonography can be of diagnostic value. An attempt at hydrostatic reduction is often unsuccessful. A high frequency of organic lesions precipitating intussusception warrants early surgical intervention.

Keywords: Intussusception, children

Intussusception is considered to be a readily diagnosed disease because the classical clinical pattern of colicky abdominal pain, vomiting and bloody stools in a child under 2 years of age is well recognized. However the fully developed triad of cardinal symptoms has been noticed in less than 50 per cent of cases[1,2]. The presence of symptoms depends on the degree of strangulation of the bowel.

In the absence of strangulation, currant-jelly stools and vomiting (due to intestinal obstruction), abdominal distension, abnormal bowel sounds and constipation may be absent. A non-strangulating intussusception may reduce spontaneously if not protruded too far or may strangulate if it progresses. It may also stay unchanged for several days or even months. In the past intussusceptions lasting for 14 days or more have been considered to be chronic[4–6]. They are distinguished from acute forms of intussusception by a characteristic clinical pattern that is conducive to delay in diagnosis. This paper reports the clinical pattern in, and diagnostic features of, nine cases of chronic intussusception in children.

Patients and methods

The reports of all 139 patients under the age of 15 years admitted to the Department of General Surgery of the St. Canisius-Wilhelmina Hospital or to the Pediatric Surgical Centre of the St. Radboud Hospital of the Catholic University of Nijmegen from 1968 to 1988, in whom the clinical diagnosis of intussusception was supported either by radiological evidence or by laparotomy, were studied retrospectively. Nine patients had a chronic intussusception as defined above.

Results

The mean age was almost 8·5 years for the seven male and two female patients (range from 3 years and 3 months to 14 years and 2 months). Three had an intussusception of the enteric type and three were ileoileocolic intussusceptions. Two were of the ileocaecal type and there was one appendicocaecocolic intussusception. In six cases a leading point was found. All nine patients had complained of daily intermittent abdominal pain. In eight of nine cases the frequency of the attacks was five times a day or less. Seven patients vomited (also sporadically). Two patients lost blood per anus. One patient complained of constipation. In three cases a looser stool or diarrhoea was produced at a normal frequency. In five cases there was no change in defaecation. Six patients were anorexic. On physical examination the weight of three patients was below the tenth percentile and in five cases between the tenth and 50th percentile. Signs of intestinal obstruction, abdominal distension and abnormal bowel sounds were found in four cases. An abdominal mass was present in seven patients.

The mean time between the onset of symptoms and admission was 35 days ranging from 3 to 93 days. A chronic intussusception was suspected because of the continuing presence of symptoms and ill health of all children. In three cases there was a considerable delay in diagnosis of 7, 9 and 13 days after admission. In the last two of these cases diagnosis at admission was of an appendix mass. In eight cases diagnosis was reached preoperatively: by clinical presentation (two cases), by barium enema examination (three cases), by small bowel follow-through meal (one case) and by ultrasonography (two cases). A plain abdominal radiograph of three patients showed air–fluid levels in dilated bowel loops on the day the diagnosis of intussusception was reached.

All children were operated on. An attempt at hydrostatic reduction was made in four cases but without success. In three of these cases an organic lesion was found. At laparotomy the fourth case was found to have undergone reduction. Although, retrospectively, an intussusception could also be seen on an earlier barium enema, this was the only case where a recurrent acute intussusception could not be ruled out with certainty. In four patients manual reduction was performed easily, in one case followed by enterotomy and in another by a small resection of viable jejunum because of a tumour which turned out to be a fibroid polyp. In two cases with a duration of 93 and 56 days manual reduction could only be achieved with great difficulty because of adhesions after which ileocaecal resection was done because of questionable viability. Partial ileal resection without manual reduction, because of possibly non-viable bowel, was performed in two cases with a duration of 16 and 21 days.

Discussion

Strangulation of the bowel can occur early or late in the course of an intussusception. An intussusception lasting more than 14 days is an uncommon condition. The incidence is estimated at 5 per cent of all intussusceptions. Under the age of 2 years, when most acute intussusceptions happen, an incidence of 3 per cent has been calculated while over that age it was 10 per cent[7]. This suggests that at an older age the anatomy allows an intussusception to occur without any significant impairment of the blood supply. On the other hand the possibility remains that delay in diagnosis, caused by the older age of the child, permits a non-strangulated intussusception to last more than 14 days.

Chronic intussusceptions distinguish themselves from acute intussusceptions by less severe abdominal pain and vomiting, a lower percentage of rectal bleeding and a higher percentage of diarrhoea[1–3,5,7]. A striking feature is the significant weight loss in many children with chronic intussusception due to long-standing anorexia and nausea or to the underlying causative factor involved[5,7].

In addition to small bowel follow-through and barium enema, ultrasonography can be of diagnostic value particularly when a mass is found[5,8–11]. The sonographic picture of intussusception is characteristic. A cross-section through the

0007-1323/89/080815-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

apex shows a target-like pattern. Scanning through the more proximal intussuscepted bowel demonstrates an image composed of two concentric rings and an inner circular area. Scans along the longitudinal axis exactly through the centre of the intussusceptum show four parallel stripes of low echogenity, delineating three reflective areas. Longitudinal scans not through the centre of the intussusceptum demonstrate three stripes of low echogenity separated by two hyper-reflective stripes.

Attempts at hydrostatic reduction of chronic intussusceptions have not been very successful in the past[5,12]. The high incidence of organic lesions is another reason for early surgical intervention, the more so as in older children this organic lesion sometimes turns out be a lymphoma[12]. At laparotomy manual reduction can often be done with ease[5,12]. In the case of irreducibility, questionable viability of the bowel and suspicion of intramural pathology, resection is indicated.

Surgical treatment of carcinoma involving the vagina

P. F. Schofield, R. J. Barnard and V. R. Tindall

Christie Hospital, Manchester M20 9BX, UK
Correspondence to: Mr P. F. Schofield

When tumours of the vagina or tumours of the uterine cervix involving the vagina are treated by operation, it is often necessary to excise a substantial part of it producing subsequent sexual problems. Attempts to create a new vagina by skin grafts[1,2] and amnion[3] have had some degree of success and there have been some favourable reports of using the sigmoid colon for this purpose[4,5]. When tumours involving the vagina are extensive, the operation may involve an even wider excision removing the bladder and urethra (anterior pelvic clearance). After cystectomy, the ureters are transplanted into an isolated loop of bowel. This has usually been a piece of ileum but sigmoid colon can be used for the conduit. We have found that it is possible to use sigmoid colon to create a new vagina and to create a urinary conduit in the same patient. The operation is described with the initial experience.

Surgical technique

The operation is carried out through a vertical, midline incision extended to the left of the umbilicus into the upper abdomen. The anterior or central clearance is performed with dissection from both the abdominal and perineal aspects but the vulva and vestibule are left *in situ*. The left colon is fully mobilized up to and including the splenic flexure, carefully preserving the blood supply. Two isolated loops of sigmoid colon are fashioned, preserving the sigmoid branches from the inferior mesenteric artery (*Figure 1a*). The mesosigmoid is split in a fan-shaped manner down to the stem of the inferior mesenteric artery, dividing the marginal artery in three places but ensuring that there is a feeding sigmoid branch into each of the two proposed loops (*Figure 1b*). The bowel is divided near the junction of the descending colon and the sigmoid at the rectosigmoid junction and at some convenient point in the mid-sigmoid (*Figure 1c*). The two isolated loops thus prepared are displaced to the right; bowel continuity is re-established by end-to-end anastomosis.

The lower loop is used to create the new vagina. The end is grasped by tissue forceps passed up from the perineal wound. The perineal operator draws the loop down and sutures it to the introitus with absorbable sutures (Vicryl®, Ethicon Ltd., Edinburgh, UK). The upper end of the loop is closed.

The upper loop is used as the urinary conduit, the ureters are anastomosed to its proximal end and the distal end is brought out through the right rectus and is sutured to the skin of the right iliac fossa as a urinary stoma.

Results

This operation has been undertaken on five patients. There was no significant early postoperative morbidity. The urinary loop functions satisfactorily and there is normal renal function. The new vagina has remained of adequate calibre but dilatation has been required in one patient. Sexual function is satisfactory in three of the five patients. One patient has not, as yet, undertaken sexual activity and one patient had early tumour recurrence and never 'used' the neovagina.

Discussion

This operation offers advantages to young women who need a radical anterior pelvic clearance including excision of the vagina. In particular, reconstruction of the vagina is immediate, without adding to the severity of the operation because some bowel has to be mobilized and isolated to fashion the urinary conduit. Although transplantation of the ureters into the intact colon may cause severe metabolic problems, this does not pertain to the transplantation of the ureters into a short isolated segment of colon used as a conduit[6]. A short, detached loop of ileum or colon is equally effective in carrying the urine to

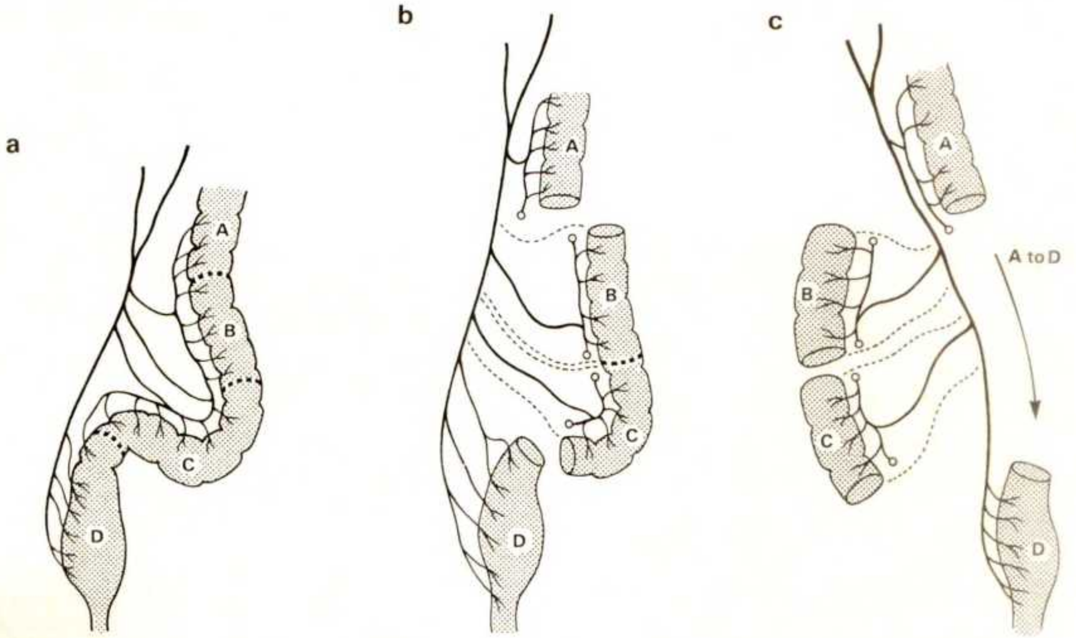

Figure 1 **a** *The sigmoid colon with its blood supply, showing the points of section:* **b** *note the preservation of the blood supply to produce two loops for the neovagina and urinary conduit.* **c** *The loops are separated; the large bowel is reanastomosed*

the skin surface from the transplanted ureters[7]. Because the colon rather than the ileum is used for the isolated conduit, there is only one intestinal anastomosis instead of two, which may well reduce the hazard of surgery. It may be argued that a colorectal anastomosis would be more hazardous than using an ileal anastomosis but this is not our experience. In expert hands, the risk of leakage from either type of anastomosis is very low[8].

There are several previous reports of employing colon to fashion a vagina for congenital absence of the structure; the results of these procedures confirm that the colon makes a satisfactory and usable vagina[5,9]. Previous experience indicates that a colonic loop makes an acceptable substitute for the vagina but the cases reported here show that it is possible to fashion a urinary conduit and a vagina from the sigmoid colon while carrying out a primary colorectal anastomosis.

Pelviureteric junction obstruction and recurrent abdominal pain in childhood

H. C. Ward and
R. J. Brereton

Queen Elizabeth Hospital for Children, Hackney Road, London E2 8PS, UK
Correspondence to: Mr H. C. Ward, Hospital for Sick Children, Great Ormond Street, London WC1 3JH, UK

Three cases of recurrent abdominal pain due to pelviureteric junction obstruction in childhood are presented. Ultrasound is useful in confirming the diagnosis and pyeloplasty is recommended.

Keywords: Abdominal pain, pelviureteric obstruction, childhood

More than 10 per cent of children complain of recurrent abdominal pain but few will have organic pathology. Pelviureteric junction obstruction was shown to be the cause in one of 100 such children studied by Apley[1]. Conversely, only one of 32 children with pelviureteric junction obstruction reported by O'Donnell had a history of recurrent abdominal pain[2]. These texts may give the impression that this mode of presentation is rare in children, resulting in clinicians failing to consider the diagnosis. Three children with recurrent abdominal pain and pelviureteric obstruction are presented to illustrate the problems of diagnosis and a policy of investigation of children with recurrent abdominal pain is suggested.

Case reports

Case 1

A boy aged 5 years presented with a 2-day history of severe abdominal pain and constipation. He had suffered from similar attacks of short duration during the previous 3 years. Investigations carried out elsewhere included an intravenous urogram which showed fullness of the left renal pelvis. The attacks usually followed a meal accompanied by fluids and had been attributed to intolerance to artificial food colourings. He had tachycardia but was apyrexial. There was tenderness and a suggestion of a mass in the left hypochondrium which was confirmed by abdominal X-ray. Urine microscopy showed occasional leucocytes and red cells but culture was sterile. Ultrasound examination revealed a large left renal pelvis and thinned renal parenchyma without dilatation of the ureter. At operation a fibrous stricture of the upper ureter was resected and continuity restored with an Anderson–Hynes pyeloplasty. An isotope scan carried out 6 months after the procedure showed no evidence of obstruction and he is asymptomatic.

Case 2

A 5-year-old boy presented with abdominal pain and vomiting of 24-h duration. The pain was localized to the left side of the abdomen. In the past his general practitioner had described him as 'a difficult child with recurrent bouts of abdominal pain and vomiting'. He had attended a casualty department on several occasions during a period of 2 years. When referred to a paediatrician his symptoms were attributed to reactive hypoglycaemia but this was never substantiated. He was afebrile and there was left sided abdominal tenderness. Urine microscopy and abdominal X-ray were normal. A limited intravenous urogram showed no function on the left side and ultrasound demonstrated a left hydronephrosis without dilatation of the ureter. At operation the diagnosis of pelviureteric junction obstruction was confirmed and an Anderson–Hynes pyeloplasty was performed. An isotope scan 6 months later showed equal function and no obstruction to either kidney. He remains asymptomatic.

Case 3

An 8-year-old boy complained of abdominal pain and vomiting for 24 h. He had had episodes of pain with vomiting over a period of 2 years. At the onset of his symptoms he had been admitted to hospital elsewhere and had been seen twice in the paediatric clinic of a second hospital in the 6 months before admission to our unit. His pain was ascribed to constipation, although his bowel habit was described as 'fairly regular'. He was pyrexial and moderately dehydrated. There was a large, tender mass on the left side of his abdomen. Ultrasound showed left hydronephrosis without a dilated ureter. Urine microscopy was normal. Intravenous antibiotics were started and he underwent Anderson–Hynes pyeloplasty for pelviureteric junction obstruction. He remains asymptomatic 10 months after operation and isotope excretion study shows no obstruction and good function.

Discussion

All three boys had experienced abdominal pain and vomiting for a number of years and, despite hospital consultations, unsubstantiated diagnoses had been made. Abdominal pain accompanied by non-bilious vomiting occurs in urinary tract disease and the child with pelviureteric junction obstruction may present with severe acute abdominal pain, haematuria or infection, but intermittent pain associated with vomiting is also recognized[3,4]. Therefore, abdominal ultrasound is indicated or, if this is unavailable, intravenous urography[5]. If these tests demonstrate hydronephrosis without a dilated ureter, an isotope excretion study may be helpful in establishing the diagnosis of pelviureteric obstruction and comparing the function of the kidneys.

Lateral abdominal pain may indicate important pathology in the urinary tract or, less commonly, the spleen (if left sided) or the gallbladder (if right sided). Rarer causes include adrenal tumours, especially neuroblastoma, retroperitoneal cysts and pseudocysts and, even more uncommonly, intestinal ulceration from ectopic gastric mucosa within intestinal duplication cysts or diverticula. Metastatic abscesses may occur within the iliacus or psoas muscles and are more common in recent immigrants from Africa or Asia. In this context, Apley has coined the aphorism 'The further the localization of the pain from the umbilicus, the more likely is there to be an underlying organic cause'[1]. It should be remembered, however, that young children do not localize pain well.

Recurrent abdominal pain with bilious vomiting is of great importance and all affected children should undergo barium meal examination to exclude intestinal malrotation predisposing to intermittent midgut volvulus[6]. Failure to appreciate the significance of these symptoms may result in intestinal infarction. Other causes of recurrent pain of intestinal origin include Crohn's disease and *Ascaris lumbricoides*, the latter occurring most frequently in recent immigrants.

Recurrent abdominal pain, with or without vomiting, headache or pyrexia, is common in children. Such pain is usually felt centrally, about the umbilicus, and may be a response to stress at home or school. The child may be setting unattainable standards for himself or be under pressure to achieve beyond his abilities. It may be impossible to identify a psychological cause for the pain but the 'periodic syndrome' may be diagnosed where emotional disturbance is strongly suspected[1].

These case histories support the use of ultrasonic examination of the abdomen, to be repeated if necessary, in all children

0007–1323/89/080818–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

with recurrent abdominal pain accompanied by non-bilious vomiting. This is especially important in children with left sided pain because of the predominance of left sided pelviureteric obstruction[3]. Barium meal is the investigation of choice when the vomitus contains bile. Any diagnosis of psychological or organic cause should be based on strong clinical grounds or on the results of specific investigations.

Multiple primary retroperitoneal tumours: a unique case

J. J. Patel, I. Taylor and S. Fleming*

*University Surgical Unit and *Department of Pathology, Level F, Centre Block, Southampton General Hospital, Southampton SO9 4XY, UK*

Correspondence to: Professor I. Taylor

Primary tumours arising in the retroperitoneal space are uncommon and retroperitoneal neurilemmomas (or schwannomas) are particularly rare[1]. Pack *et al.*[2] reported only one in 120 cases of primary retroperitoneal tumours, Donnelly[3] reported one in 95 cases, Felix *et al.*[4] reported two in 53 cases and Braasch and Mon[5] encountered none in the Lahey Clinic experience between 1930 and 1960.

We report the first case, as far as we are aware, of metachronous primary retroperitoneal neurilemmomas: that is, tumours occurring in different retroperitoneal sites of the abdomen and pelvis at different times.

Case report

The patient, a 47-year-old white caucasian man, presented initially as an emergency, with central lower abdominal pain, right shoulder tip pain, dysuria and recent 1-stone (6·4 kg) weight loss. On examination there were signs of peritonitis and a large, hard, irregular mass arising from the right side of the pelvis. No stigmata of von Recklinghausen's neurofibromatosis were apparent. Laparotomy revealed a haemoperitoneum and a hard, nodular tumour, 14 × 10 cm, arising from the right lateral wall of the pelvis. There was no evidence of local invasion, and venous bleeding was profuse. The tumour was removed and histology revealed low grade sarcomatous change in a neurofibroma.

The patient remained well and was discharged from follow-up after 3 years. He re-presented, again as an emergency, at the age of 56 years, with an identical history and similar signs to his previous presentation. On this occasion the mass was palpable suprapubically and rectally. At laparotomy there was a tumour, 16 × 10 × 10 cm, in the central pelvis adjacent to the bladder and rectum. It was well encapsulated and mobile. Histology was reported as practically identical to the previously excised tumour but it was considered to be a malignant fibrous histiocytoma. The patient was now followed up with regular 6-monthly abdominal and pelvic ultrasound examinations.

At the age of 63 years, 16 years after he originally presented, a 5-cm mass in the left side of the pelvis was detected on ultrasound examination. A computed tomographic scan (*Figure 1*) revealed this to be 4·5 cm in diameter, lobulated and situated in the posterolateral pelvis, separated from the bladder by a fat plane. The tumour was excised at laparotomy and reported to be a low grade fibrosarcoma, identical to previous excisions, and not a malignant fibrous histiocytoma, owing to the lack of pleomorphism.

Eighteen months later, at the age of 64 years, a follow-up ultrasound showed a 7-cm mass inferior to the left kidney. This was confirmed by computed tomographic scan (*Figure 2*). At laparotomy, a 10-cm spherical tumour, posterior to the splenic flexure and inferior to the spleen, was completely excised. After extensive pathological discussion the tumour was now thought to be a cellular schwannoma, because it was a spindle cell tumour with mild pleomorphism, no necrosis and occasional mitotic figures with predominant Antoni A areas lacking cellular palisading and Verocay bodies (*Figure 3*). In addition, immunocytochemical staining with S100 protein showed patchy positivity consistent with the diagnosis. On review, histologies were identical.

Discussion

Following an extensive literature search we have been unable to find a case of multiple primary retroperitoneal tumours occurring at different sites within the abdomen and pelvis. Malignant retroperitoneal tumours are four times more prevalent than benign tumours[6]. The neurilemmoma is a benign tumour with a well defined form that resembles neoplasms of fibroblastic origin. The tumours removed in this patient were not recurrences because they were in different sites in the retroperitoneum, well encapsulated and completely excised, with no gross or histological evidence of invasion. Most patients with a solitary neurilemmoma are young to middle-aged adults[7]. Our patient was aged 47 years on initial presentation.

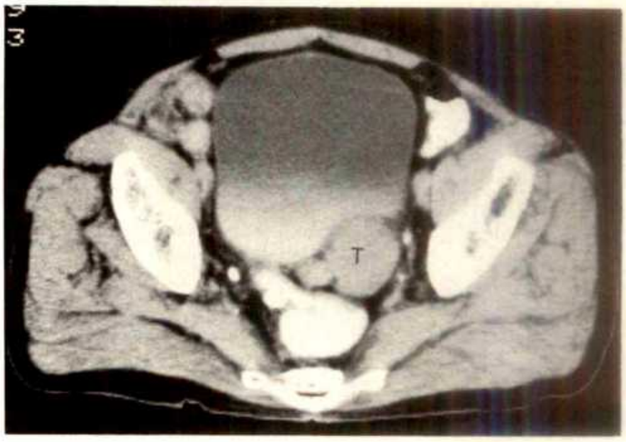

Figure 1 *Computed tomographic scan showing a 4·5-cm lobulated mass (T) on the left side of the pelvis, separate from bladder*

0007-1323/89/080820-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

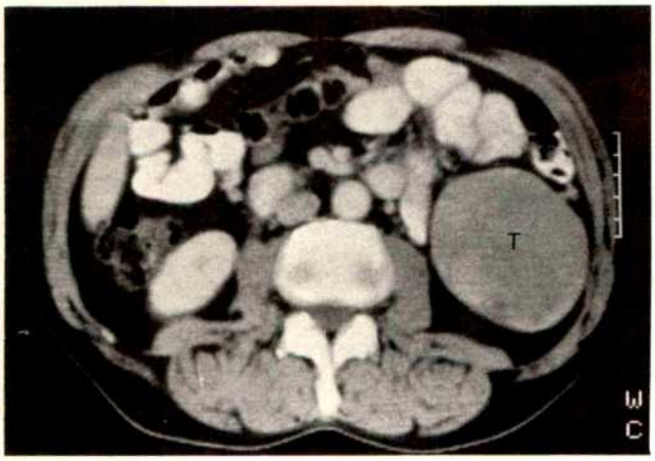

Figure 2 *Computed tomographic scan showing a 7-cm mass (T) inferior to the left kidney*

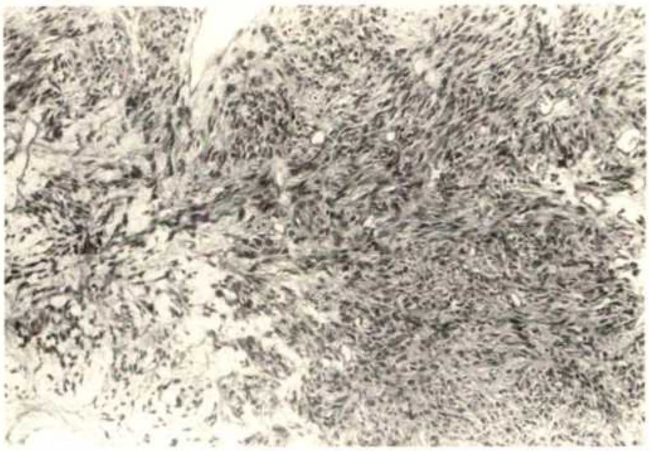

Figure 3 *Photomicrograph showing a whorled pattern of highly cellular spindle cell areas within the tumour but adjacent less-cellular areas with a myxoid stroma are also seen (× 25). Tumour removed when patient aged 64 years*

There are only 42 reported cases of retroperitoneal neurilemmoma in the literature[8]. None of these was multifocal. A high proportion of solitary neurilemmomas occur in the region of the head and neck, especially the spinal nerve roots, acoustic nerve and other cranial nerves[8]. In the present case all the lesions were retroperitoneal and there was no evidence of lesions elsewhere.

The diagnosis of von Recklinghausen's neurofibromatosis was discounted because the patient had none of the stigmata seen in the recognized different forms of neurofibromatosis[9]. The terminology of peripheral nerve sheath tumours has been confused by the interchangeable use of neurilemmoma, neurofibroma, schwannoma and neuroma. Current opinion believes that the neurilemmoma (or schwannoma) and the neurofibroma are separate histological and clinical entities, although their cell of origin in both cases is the Schwann cell[1].

The histopathological diagnosis of cellular schwannoma was reached after careful review of all the sections. This is a variant of neurilemmoma that has been reported by Woodruff *et al.*[10], and more recently by Fletcher *et al.*[11]. Both groups noted that it may be mistaken for a malignant tumour[10,11]. This is substantiated by our case, diagnoses of low grade fibrosarcoma and malignant fibrous histiocytoma having been made before the final diagnosis was reached. However, before Woodruff and Fletcher no classification of cellular schwannoma actually existed and at the time of this patient's initial presentation these tumours were considered to be low grade fibrosarcomas. Cellular pleomorphism is not by itself an indication of malignancy in neurogenous tumours[1]. In Woodruff's series[10] of 14 cellular schwannomas, six had been mistaken for either malignant fibrous histiocytoma, leiomyoma or sarcoma, but follow-up has so far shown the tumour to behave in a benign fashion. Similarly, five of the 18 cases in the series of Fletcher *et al.*[11] had previously been diagnosed as sarcomas.

Surgical management of neutropenic enterocolitis

J. B. Koea and
J. H. F. Shaw

University Department of Surgery,
Auckland Hospital, Auckland,
New Zealand
Correspondence to:
Professor J. H. F. Shaw

Three cases of histologically confirmed neutropenic enterocolitis, each presenting as an acute abdomen in patients with leukaemia are presented. All three patients presented with fever and abdominal pain within 14 days of completing a course of chemotherapy. Signs of peritonitis localized to the right iliac fossa developed in each patient, in spite of aggressive antibiotic therapy and bowel rest. All three patients were found to have non-viable caecum at laparotomy and were treated by right hemicolectomy. Primary ileocolic anastomosis was performed in one patient, who recovered following a stormy postoperative course owing to sepsis. Two patients underwent formation of an ileostomy with distal mucous fistula and each recovered with minimal postoperative complications; secondary anastomosis was performed electively in both cases. The difficulty in diagnosing neutropenic enterocolitis preoperatively is discussed and the place of non-operative management is reviewed but we recommend surgical intervention as a means of ensuring removal of a localized septic focus until marrow regeneration occurs.

Keywords: Colitis, leukaemia, neutropenia

In the last two decades the aggressive use of multiagent chemotherapy has prolonged the survival for many patients with haematological malignancy[1]. As a result, new complications of both the disease process and the treatment employed are presenting for management. Neutropenic enterocolitis (also known as typhlitis[2], ileocaecal syndrome[3] and necrotizing enteropathy[4]) is a life-threatening condition from which, until 1979, only two patients had survived[5,6]. While current series quote a survival rate of 50–80 per cent[7–9], no clear management policy has been established. Neutropenic enterocolitis has been reported in patients with acute leukaemia[2,3,8], aplastic anaemia[9], cyclic neutropenia[10,11] and (rarely) solid tumours[4], and it may present to surgeons working in a hospital with a specialist haematology unit. Historically, the poor long-term prognosis for many of these patients engendered an attitude of surgical conservatism[3,12]. However, with the increasingly prolonged survival and the improved management of the immunocompromised haematology patient this attitude is clearly no longer tenable.

This paper presents our experience with three cases of neutropenic enterocolitis managed successfully with selective surgical intervention.

Case reports

The haematology department at Auckland Hospital services a population of at least one million. The senior author (J.H.F.S.) provides the surgical consultation for this department and the three cases reported are a true representation of the incidence of neutropenic enterocolitis in the Auckland area. The three cases were seen over a 4-year period.

Case 1

A 13-year-old girl with acute myeloid leukaemia who had completed three courses of chemotherapy (two courses of daunorubicin and cytosine arabinoside and one course of meta amsidyl amsicrine (Park Davis, Auckland, New Zealand) and cytosine arabinoside) was routinely readmitted to hospital 7 days after her last course of chemotherapy. On admission she was well, although thrombocytopenic with a white cell count of $0{\cdot}4 \times 10^9$/litre. Two days later she became febrile (39°C) and complained of abdominal pain. Examination showed no other obvious source of sepsis except for her abdomen, which was diffusely tender with moderate tenderness in the epigastrium. Bowel sounds were present and there were no signs of peritoneal irritation. Blood cultures were taken, which showed no growth after 7 days incubation, and triple antibiotic therapy was commenced with flucloxacillin, gentamicin and metronidazole. The next day the patient's condition had worsened, with a temperature of 40°C and severe abdominal pain, both in the epigastrium and right iliac fossa. There were no signs of peritoneal irritation at this stage. The surgical service was consulted and a presumptive diagnosis of neutropenic enterocolitis was made. A conservative approach was adopted and she was reviewed serially. A supine abdominal X-ray did not demonstrate any abnormality, and stool assay for *Clostridium difficile* toxin later proved to be negative. Within 24 h the patient's condition had deteriorated further, with right sided peritonism becoming prominent, in association with vomiting, diarrhoea and signs of circulatory instability. At laparotomy the serosal surface of the caecum was noted to be mildly congested. No perforation or faecal soiling of the peritoneal cavity was present and a right hemicolectomy with primary ileocolic anastomosis was performed. Histologically this specimen showed mucosal ulceration consistent with neutropenic enterocolitis. Postoperatively the patient had a stormy course with systemic sepsis requiring inotropic support for 4 days. Her blood pressure and vital signs stabilized on the fifth postoperative day, at which time her peripheral blood showed regeneration, with a white cell count of 5×10^9/litre. She made a good recovery and had one further course of chemotherapy without complication before achieving remission.

Case 2

A 14-year-old boy, diagnosed as having acute myeloid leukaemia, was commenced on treatment with cytosine arabinoside and meta amsidyl amsicrine. One month later he was readmitted to hospital with anorexia, fever and abdominal pain localizing to the right iliac fossa. He was commenced on intravenous amikacin, ticarcillin and flucloxacillin. The surgical service was consulted and a diagnosis of probable appendicitis was made. His symptoms settled with the addition of metronidazole to his antibiotic regimen. During the following month he was admitted four times for fever, rigors and abdominal discomfort. Each time these symptoms resolved with parenteral antibiotic therapy consisting of ticarcillin, amikacin and metronidazole. Of the six sets of blood cultures taken during these admissions, one culture plate grew *Staphylococcus aureus* and one grew *Escherichia coli*. An elective appendicectomy was performed 1 month after the patient's initial admission and a good recovery ensued. During this admission a bone marrow biopsy showed a persisting haematological abnormality and he commenced chemotherapy with daunorubicin and cytosine arabinoside. He was readmitted to hospital 14 days after the third course of chemotherapy complaining of fever (39°C) and generalized abdominal pain. Examination showed that he was tender in the right renal angle. The white cell count on admission was $0{\cdot}12 \times 10^9$/litre. Blood cultures were taken (no growth after 7 days

0007-1323/89/080821-04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

incubation) and parenteral antibiotic therapy was instituted. During the following 24 h he remained febrile (40°C) and developed signs of peritonism in the right side of the abdomen. Abdominal X-ray showed a lack of psoas shadows bilaterally. Abdominal computerized tomographic scanning showed free fluid, particularly in the right paracolic gutter, but no focal collections. Stool analysis was later positive for *C. difficile* toxin, while urinary microscopy showed no abnormality. An exploratory laparotomy undertaken the following day showed no significant pathology and no surgical resection was undertaken. However, because the patient's condition continued to deteriorate, with gross abdominal pain and signs of sepsis, a further laparotomy was carried out 3 days later. Intraoperatively the caecum appeared normal but a presumptive diagnosis of neutropenic enterocolitis was made and right hemicolectomy was performed, with the formation of an ileostomy and a mucous fistula. Histological examination showed extensive mucosal and submucosal ulceration consistent with neutropenic enterocolitis. Review of the appendiceal histology also showed changes consistent with this diagnosis. Postoperatively the patient made a good recovery with his white cell count returning to the normal range on day 5. Secondary anastomosis was undertaken 3 months later and the patient had remained well with no recurrence of his gastrointestinal symptoms.

Case 3

A 22-year-old man, previously identified as having acute lymphoblastic leukaemia, was admitted 7 days after his last cycle of chemotherapy with cyclophosphamide, vincristine, methotrexate and prednisone. On admission he was febrile (38·5°C) with a white cell count of $0{\cdot}1 \times 10^9$/litre. Physical examination revealed no obvious source of sepsis. Once blood cultures were taken (no growth after 7 days culture) antibiotic therapy was commenced with amikacin, ticarcillin, flucloxacillin and metronidazole. During the following 2 days the patient's condition deteriorated, with continuing fever, generalized abdominal pain and peritonism, and guarding in the right iliac fossa became prominent. The patient vomited once. Bowel sounds were absent and a fullness was palpable in the right iliac fossa by the third day of admission. The surgical service was consulted and a diagnosis of neutropenic enterocolitis was made. The patient was taken to theatre where a gangrenous caecum was found. A right hemicolectomy was performed, with the formation of an ileostomy and a mucous fistula. Histology of this specimen confirmed the clinical diagnosis. Postoperatively the patient made a good recovery. On the tenth postoperative day a collection of straw-coloured fluid (no growth after incubation for 7 days) was drained percutaneously from the supravesical area. Recovery of normal levels of circulating white cells began on the second postoperative day and increased to 5×10^9/litre by the seventh day. The bowel was reanastomosed electively 3 months later with no complication. The patient recovered normal bowel function and suffered no further gastrointestinal upset but unfortunately died following relapse of his leukaemia 5 months after his initial operation.

Discussion

The incidence of neutropenic enterocolitis is unclear. Various investigators have reported incidences between 1 and 46 per cent in patients with leukaemia[4,13,14]. The most comprehensive assessment has been that of Moir and Bale[13] who found that it was a major cause of death in 38 per cent of 50 consecutive autopsies in leukaemic patients. In addition, pathological changes characteristic of neutropenic enterocolitis were present in the gastrointestinal tract of 46 per cent of these patients. In contrast, Amromin and Solomon[4] found evidence of neutropenic enterocolitis in 22 per cent of a series of leukaemic autopsies between 1956 and 1961. Whether this indicates an increase in absolute incidence or simply reflects improved diagnosis and investigation is unclear. However, it does indicate that the disease causes significant morbidity and mortality in patients with leukaemia. Our three cases were collected over a 4-year period, during which time 12 patients with symptoms suggestive of an acute abdomen were seen in the haematology unit. The three cases we have reported were the only patients to require operation; the remaining nine patients settled with non-operative measures. Other investigators have suggested that neutropenic enterocolitis has a spectrum of severity ranging from mild gastrointestinal upset to gross peritonism and systemic sepsis[7,8]. Our experience is consistent with this. It is patients in the latter group who will require surgical intervention.

The aetiology of neutropenic enterocolitis is poorly understood. It characteristically affects the right colon and caecum during periods of profound neutropenia[7–10], particularly in patients with marrow suppression due to a recent course of chemotherapy, typically with cytosine arabinoside[7,8]. The presence of enteric bacteria, particularly the bacillus *Clostridium septicum*, in necrotic areas of the right colonic wall is a consistent finding[9,13,15] and suggests that neutropenic enterocolitis is primarily an infective lesion in an immunocompromised patient. The presence of systemic Gram-negative sepsis in a significant number of these patients is consistent with this hypothesis[7,8]. Various mechanisms of injury to the intestinal mucosa which could aid bacterial invasion have been suggested. These include shock leading to submucosal ischaemia, necrosis of leukaemic infiltrates, bleeding due to a haemorrhagic diathesis[4], abnormal intestinal flora due to aggressive antibiotic therapy[13], and the administration of prednisone[5] or cytotoxics[16]. The relative contribution of these factors to the pathogenesis of neutropenic enterocolitis is unclear, as Geelhoed *et al.*[11] showed that ulcerative caecal lesions may occur in patients with severe neutropenia without any localized predisposing factors.

The characteristic lesion of neutropenic enterocolitis is mucosal ulceration of the caecum and right colon without an accompanying inflammatory response[13]. Other parts of the gastrointestinal tract may be affected but in general these lesions are self limiting[7], while those in the caecum may progress from severe mucosal ulceration to full thickness gangrene. The reasons underlying the increased severity of this disease in the caecum are not clear. Ikard[17] has suggested that, because the colon may have less vascular perfusion than the remainder of the bowel[18,19], particularly during distension[20], and as the caecum is more distensible than the remainder of the colon, submucosal ischaemia can develop within the caecal wall. The impairment in bowel motility seen in inactive and ill patients compounds this problem, leading to mucosal compromise and infection.

The diagnosis of neutropenic enterocolitis remains difficult and a significant number of patients are diagnosed at post mortem[2,7]. As in our three cases, the principal presenting complaints are fever, abdominal pain localizing to the right iliac fossa, vomiting, and watery diarrhoea which may be positive for occult blood. Frank melaena is unusual. Moir *et al.*[7] found that fever was present in all of their 16 patients, as was abdominal pain (this was right sided in seven patients and generalized in nine patients). All but one of these patients had diarrhoea (blood was present in the stool of half of them), while seven vomited or had abdominal distension at some time during their clinical course. Shamberger *et al.*[8] have added the proviso that the presence of these symptoms in the setting of neutropenia (an absolute neutrophil count of less than $1{\cdot}0 \times 10^9$/litre) and cytotoxic therapy should alert the surgeon to the correct diagnosis.

While the symptoms of neutropenic enterocolitis are non-specific, other factors may complicate the diagnosis. Administration of prednisone may mask or ameliorate local symptoms[4], while various cytotoxic agents (e.g. vincristine) are well known causes of abdominal discomfort and gastrointestinal upset[21]. Similarly Sickles *et al.*[22] have reported that physical findings may be minimal in neutropenic patients with severe sepsis.

Our second patient also emphasizes that other causes of the acute abdomen may occur in conjunction with neutropenic enterocolitis. Data from other oncology centres indicate that there is a 5 per cent incidence of acute abdomen in patients with haematological malignancy[6,23,24] and that neutropenic enterocolitis is the cause in under half of them. This patient had his appendix resected 6 weeks before having a hemicolectomy. Revision of the appendiceal histology after the hemicolectomy revealed changes consistent with neutropenic enterocolitis. This patient also had *C. difficile* toxin isolated from his stool although a histological diagnosis of neutropenic enterocolitis was made in the resected colon. The leukaemic patient is at risk of colonization with *C. difficile* due to the aggressive antibiotic policies pursued in these patients[25].

A clinical diagnosis of neutropenic enterocolitis may be suggested by radiological evidence of partial distal small bowel obstruction, thickened and irregular mucosal folds in the caecum, the presence of air in the bowel wall, or a right sided soft tissue mass representing a fluid-filled caecum. Ultrasound and computerized tomographic scanning have also been used to demonstrate a thickened bowel wall[26,27]. Barium enema has been advocated[28], although the danger of perforating a non-viable caecum lends significant risk to this procedure. Geer *et al.*[29] have used peritoneal lavage in diagnosis because this detects significant peritoneal soiling. However, this is only useful in the diagnosis of advanced neutropenic enterocolitis and cannot differentiate between it and other causes of intestinal perforation, such as necrosis of leukaemic infiltrates. Consequently the diagnosis must rest on a high index of suspicion and repeated physical examination, looking for persistence or worsening of abdominal signs[8,30,31].

The management of neutropenic enterocolitis is controversial but a rational approach to treatment can now be formulated. Diagnosis remains the first step in successful management. The fact that this did not occur until after death in a significant number of patients in some studies[6,7] indicates that this remains an area of confusion. There is general agreement that early management should be conservative[7,30]. A standard antibiotic regimen and bowel rest should be commenced. If signs of obstruction are present then nasogastric suction should be commenced. The indications for surgical intervention are less clear. Moir *et al.*[7] and Shaked *et al.*[12] have reported recovery rates of 100 per cent in patients managed without surgical intervention. In contrast, Exelby *et al.*[6] found a mortality rate of 100 per cent in conservatively treated children. However, of the patients treated conservatively by Moir *et al.*[7], one developed a postinflammatory colonic stricture, while two other patients later died of recurrent neutropenic enterocolitis. Thus it is clear that there is a place for conservative treatment but it is associated with significant risks. Our experience is in agreement with that of other centres[7,8,17] in that conservative treatment is warranted initially but the indications for surgical intervention are the same as in an immunocompetent patient, namely: (1) persistent gastrointestinal bleeding after correction of coagulation abnormalities; (2) radiological and/or clinical evidence of imminent intraperitoneal perforation; and (3) general deterioration, or the requirement of large volumes of intravenous fluid or pressor support suggesting uncontrolled sepsis.

The choice of surgical procedure is controversial and to some degree depends on intraoperative findings. Consistently poor results have been reported in patients undergoing appendicectomy or caecostomy for neutropenic enterocolitis[12,30]. Kunkel and Rosenthal[28] have suggested that, in all but very advanced cases, the serosa remains intact despite extensive underlying mucosal damage as these patients are unable to mount an inflammatory response. Thus the poor results obtained with 'minor' surgery may reflect unrecognized extensive disease that was inadequately treated. Case 2 illustrates this point. This patient continued to be symptomatic despite appendicectomy and a caecum which appeared normal at a subsequent laparotomy; hemicolectomy performed at a third laparotomy revealed extensive mucosal disease. The three patients we have reported made good recoveries following standard right hemicolectomy. Histology of all three resected specimens showed extensive disease, although this was not always apparent intraoperatively. Primary ileocolic anastomosis is feasible in the patient without gross peritoneal contamination[7,30,31] as in case 1. However, because the majority of these patients are severely immunocompromised and have significant sepsis, a defunctioning ileostomy with a mucous fistula is an acceptable alternative[7,30,31]. If the stomas are exteriorized close together, the ileostomy can be reversed extraperitoneally once the patient's condition has stabilized, thereby reducing the risk of sepsis. Certainly the complicated postoperative course due to sepsis that occurred in case 1 was avoided in cases 2 and 3. This is particularly notable as case 3 had obvious caecal gangrene at operation. Moir *et al.*[7] have shown that postoperative sepsis is usually the rule in these patients until peripheral neutrophil counts recover. In this respect, granulocyte infusions have been used postoperatively and there is anecdotal evidence that they are beneficial[5,7,23]. Shaked *et al.*[12] have suggested that the return of blood neutrophil levels to normal is the most important determinant of survival and that surgery is unimportant in this regard. While this may be true (and our experience would support it), we believe that the role of surgical intervention in these patients is to remove a localized septic focus, thereby ensuring survival until marrow regeneration occurs. Severe neutropenia is not a contraindication to surgery[24,30,31] and it is clear that untreated peritonitis in the leukaemic patient is uniformly fatal[31].

Subclavian arteritis

N. D. Karanjia and A. E. B. Giddings

Royal Surrey County Hospital, Egerton Road, Park Barn, Guildford, Surrey GU2 5XX, UK
Correspondence to: Mr A. E. B. Giddings

Subclavian arteritis is a rare cause of upper limb ischaemia. It affects large arteries, either unilaterally or bilaterally, although bilateral presentations may not be synchronous. Symptoms are typically shoulder girdle pain, arm 'claudication' or digital ischaemia and diagnosis by arteriography is required. The presentation, clinical findings, investigation and treatment of five patients with subclavian arteritis are analysed.

Patients and methods

A register of patients presenting with a clinical diagnosis of arteritis was kept over 8 years. Of the 104 patients included, five were identified as having subclavian arteritis. They were all women with an age range of 32–70 years (mean 58 years).

Results

The most frequent symptom, affecting four patients, was an aching in the shoulder girdle of the affected side; this was particularly bad at night. Although it bore no relation to movement, it was usually thought to be of musculoskeletal origin. The fifth patient complained of pain on elevation of the arm. Three of the patients developed arm 'claudication', one presented with cyanosis of a cold hand and another with ulceration of the index finger. In two of three patients with bilateral involvement, the presentation was synchronous, but in the third, the syndrome of pain in the shoulder, arm claudication and episodic ischaemia of the hand, recurred in an identical manner on the opposite side 18 months after successful treatment of the first side with steroids. All patients had reduced brachial artery pressure in the affected arm and the distal pulses were reduced or absent. Erythrocyte sedimentation rate measurements in four patients were greater than 40 mm/h in two of them, and one had an unexplained hypochromic anaemia. Delay between the onset of symptoms and diagnosis varied from 3 to 17 weeks, with an average of 9 weeks. Arch and selective arteriography was the most useful diagnostic investigation. Initial treatment with prednisolone, 30–60 mg daily in divided doses, abolished shoulder pain in all patients within 3 days. In three of five patients, arm claudication improved and a skin ulcer healed without further measures. The other two had persistent critical distal ischaemia with rest pain and were treated surgically by subclavian and brachial thrombectomy. Biopsy of the artery was also performed. One of these patients subsequently had a cervical sympathectomy but in no case was surgical bypass required. There were no significant complications and symptoms resolved. Histology of the biopsies showed a panarteritis with intimal thickening and a chronic inflammatory cell infiltrate.

Discussion

Subclavian arteritis is a variety of giant cell arteritis, which was initially thought to involve only the cranial vessels. In a recent review, however, Klein *et al.*[1] found evidence of large peripheral artery involvement in 34 of 248 patients with cranial arteritis, four of whom presented exclusively with claudication of the arm and absent pulses as the initial manifestation of the disease. Classically, giant cell arteritis affects older patients in whom medium-sized muscular arteries are involved, although larger elastic arteries may also be affected. The lesions show intimal thickening, dense chronic inflammatory cell infiltrate, multinucleate giant cells and disruption of the internal elastic lamina[2]. These histological features are identical to those seen in Takayasu's arteritis[3,4], but the latter disease has a distinct geographical and clinical pattern affecting younger oriental women[1,5].

In Takayasu's disease an initial inflammatory phase involves the aorta and largest elastic arteries with a panarteritis. Later medial fibrosis and intimal damage result in stenoses, thromboses, aneurysm formation and dissection. Unlike giant cell arteritis, renal arterial involvement is common, leading to hypertension[1,5], and, in addition, medium-sized muscular arteries (e.g. superficial temporal) are rarely implicated.

The aetiology of subclavian arteritis is unknown. The presentation, histological features and response to treatment could be consistent with an autoimmune lesion, although autoimmune profiles were normal in two of our patients and

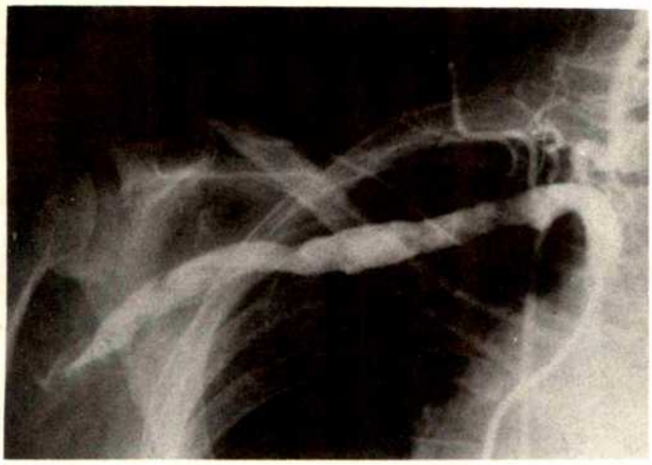

Figure 1 *Arteriography in subclavian arteritis showing segmental ectasia, irregular stenoses and occlusion. Collateral vessels are few in number and of poor calibre*

weakly positive in one. Two of the patients had a previous exposure to tuberculosis and an association with this is possible.

The diagnosis is often delayed. It should be considered in all patients with severe shoulder girdle pain causing sleeplessness, associated with distal ischaemia. Microembolism of the digital vessels requires early diagnosis and treatment as collateralization of occluded digital vessels is poor.

Early arteriography is advised. This demonstrates segmental ectasia and irregular stenoses or occlusions involving the subclavian or axillary arteries. Proximal and distal vessels are of normal size but collateral vessels are of poor calibre and are few in number (*Figure 1*). Intra-arterial clot shows as filling defects. In Takayasu's disease, stenoses, aneurysms and arterial thromboses are evident but, in contrast, collateral vessels are abundant[6]. Gotsman *et al.*[7], discussing selective angiographic features in aortoarteritis, describe a constant feature in subclavian disease with involvement of the vessel beyond the origin of the costocervical trunk as it crosses the first rib. Discrete plaques or intimal ulcers, suggesting focal atherosclerosis, are usually absent in both of the above conditions[1-5].

Initial treatment with steroids in high dosage achieves remission, allowing later reduction to a maintenance dose of 5–15 mg daily. Although a high erythrocyte sedimentation rate is a diagnostic pointer and, if raised, is useful in monitoring response to treatment, a low rate does not preclude the diagnosis. If medical treatment fails, surgical options include thrombectomy, sympathectomy or bypass grafting. In our patients, thrombectomy and sympathectomy were effective in controlling acute limb ischaemia, allowing steroids time to reduce the inflammation. By contrast, Drury and Pollock[8] treated six patients who had subclavian arteriopathy with bypass grafting or excision and interposition grafting of affected areas, with good results. In none of their cases were steroids used and perhaps their use could have avoided the need for surgery.

In our patients, steroids and limited surgery were sufficient to abolish symptoms from 18 months to 5 years. Endarterectomy, which depends for its success on the separation of tissue planes, is not appropriate for these inflammatory lesions, in which the layers of the arterial wall are obliterated by transmural inflammation, but thrombectomy and sympathectomy are helpful where steroids alone are insufficient.

Abdominal aortic aneurysms: a review of current problems

T. R. Cheatle and J. H. Scurr

Department of Surgical Studies, Middlesex Hospital, Mortimer Street, London W1N 8AA, UK
Correspondence to: Mr T. R. Cheatle

This review examines the aetiology and possible methods of prevention of abdominal aortic aneurysm. The natural history of the lesion is discussed. Given its poor prognosis, surgery should be considered even when the patient is over 80 years of age, has stable cardiovascular disease and has a small aneurysm. The case for population screening is reviewed and potential areas of advance in management are outlined.

Keywords: Abdominal aorta, aneurysm, aetiology, screening

Statistics from the Office of Population Censuses and Surveys indicate that one in 70 men who die between the ages of 60 and 84 years do so from a ruptured abdominal aortic aneurysm[1]. It has been pointed out that as the proportion of the population aged over 65 years grows, so we will inevitably be faced with increasing numbers of such cases[2], and indeed there is evidence already of a rising incidence[3–5]. It is known that successful aneurysm repair results in a near normal subsequent life expectancy[6–8], while fewer than one in five survive a rupture[9,10] (less than one in ten in the case of women[5]). This represents an enormous number of potentially preventable premature deaths, given current operative mortality rates of less than 5 per cent in elective cases[11]. Current work in the field centres on attempts to answer four main questions.

1. What is the aetiology of abdominal aortic aneurysm, and is prevention feasible?
2. What is its natural history, and can patient selection be improved in the light of this knowledge?
3. How should screening be carried out, who should be screened and at what cost?
4. Are further medical or surgical advances likely in the near future?

What is the aetiology of abdominal aortic aneurysm and is prevention feasible?

Conventional teaching states that the majority of aortic aneurysms are caused by atherosclerosis, with a very small number due to other specific causes such as arteritis (more common in black populations[12]), tuberculosis and syphilis. However, the sex distribution of the disease, the familial tendency and the proneness of some atherosclerotics to develop stenosing arterial disease while others get aneurysms all imply the presence of another factor or factors besides the mere presence of atherosclerosis. Aneurysm induction in animals on an atherogenic diet has not been productive[13], although animal studies are intrinsically unlikely to be relevant in this field when one considers the surprising difference in medial structure and vasculature between man and most other mammals[14].

That a familial predisposition to aneurysm formation exists seems undeniable. Johansen and Koepsell[15] compared the family histories of 250 patients with aneurysms with those of 250 control subjects. Six of the latter group reported a first degree relative with an aneurysm, while no less than 48 of the former group had such a relative. After adjustment for age and sex, the authors conclude that an increased risk (by a factor of 11·6) attends persons with a first degree relative suffering from an aortic aneurysm. A smaller study from Kentucky[16] describes five patients, each of whom had two or more affected first degree relatives. The possible mechanisms of inheritance have been examined by Tilson and Seashore[17,18]. After looking at the genealogy in families where two or more first degree relatives were affected, they found that in over half the instances the mode of inheritance was consistent with an X-linked dominant gene. However, most of the remainder displayed inheritance from father to son (where the X chromosome of the father is, of course, not transmitted), suggesting an autosomal dominant pattern; nevertheless, the sex ratio in the latter group was still strongly biased towards males. The authors suggest that two distinct forms of the disease may exist: one X-linked and the other inherited as an autosomal dominant gene.

Having postulated an inherited, genetically based deficit we must ask what the physical expression of this defect might be; in other words, what biochemical abnormality is it that exists in these patients? Attention has focused on the activities of three enzyme systems in particular: lysyl oxidase, collagenase and elastase.

Lysyl oxidase is the enzyme which converts lysine residues to aldehydes, a necessary step in the formation of cross-linkages in collagen and elastin molecules. The aneurysm-prone *Blotchy* mouse is known to have defective cross-linkaging owing to low activity of this enzyme, which is linked to the X chromosome[19,20]; the underlying defect is a fault in the copper transport mechanism resulting in low serum levels of copper, an essential cofactor of lysyl oxidase[21]. These facts, along with observations on children with Menkes' syndrome[22] (low serum copper, kinky hair, mental retardation and dilated and tortuous arteries), prompted speculation that low copper levels might be a contributing factor in aortic aneurysm disease.

Tilson has examined copper levels in patients with aneurysms[13]. Post-mortem hepatic copper levels were measured in 13 patients who had died with or from an aortic aneurysm, and were compared with levels in 13 controls with severe non-aneurysmal atherosclerotic disease. The results showed that control subjects had a mean hepatic copper level of almost twice that of aneurysm subjects, although the difference did not attain statistical significance. A subsequent prospective study of eight aneurysm/control pairs of patients measured skin copper levels and again found that levels in aneurysm patients were roughly half those in controls, although, again, statistical significance was not achieved[23]. However, studies by Senapati *et al.*[24] have failed to confirm these findings. In addition, the aneurysms formed by the *Blotchy* mouse do not display the cystic medial necrosis so typical of human aneurysms, occur in the thoracic rather than the abdominal aorta, and are not saccular. Hence, the relevance of copper levels to the aetiology of aortic aneurysms in man is open to doubt but may be important in that subgroup of patients in whom an aneurysm is associated with generalized arteriomegaly[25].

The role of enzymatic proteolysis may be of greater importance in the pathogenesis of the condition. Work in this field dates principally from that of Sumner *et al.*[26], who found that the percentages of collagen and elastin in the walls of

0007–1323/89/080826–04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

aneurysmal aortas were significantly lower than those of non-aneurysmal atherosclerotic aortas, even in the outer layers of the wall where there is no laminated clot to act as a diluent to the measured proteins. Collagenase activity has been demonstrated to be appreciably higher in aneurysmal tissue than in non-aneurysmal tissue[27], as has elastase[28] Circulating elastase of leucocyte origin has also been shown to be higher in aneurysm patients who smoke[29]; it is thought that this is due to smoke-induced destruction of α_1-protease inhibitors. However, patients with the Leriche syndrome, who smoked as much as those with aneurysms, showed no changes in elastase activity, perhaps indicating a genetically determined difference in the response to smoking between the two groups. This may be related to the antiprotease status of the patients The principal antiprotease agent *in vivo* is α_1-antitrypsin, normally present in concentrations of 150–400 mg/dl The concentration is genetically determined It is the natural antagonist to elastase, and the relationship between the two is analogous to that between the coagulation and fibrinolytic systems. Abboud *et al.* have shown that heavy-smoking emphysema patients with the PiMZ phenotype, leading to reduced α_1-antitrypsin levels, had significantly greater neutrophil elastase activity[30] It has recently been demonstrated that the elastase:α_1-antitrypsin ratio is significantly increased in patients with aneurysms, especially those suffering rupture[31]. These two lines of research (enzyme system activities in patients with aneurysms and in those with emphysema) have recently been connected by Cronenwett and his colleagues[32]. In a prospective study of 67 patients selected for non-operative management, 30 potential risk factors were measured. The patients were followed for a mean of 36 months and the risk factors were then assessed for their predictive value with regard to aneurysm rupture. Only three factors were independently predictive of rupture diastolic blood pressure, anteroposterior aneurysm diameter and, surprisingly, the degree of obstructive airways disease.

Do these theories concerning the aetiology of aneurysms point to possible preventive measures? Even if the mode of heritability were to be completely worked out, genetic counselling seems of little relevance to a disease which rarely affects people before the age of 60 years, and which is readily treated surgically if detected before rupture occurs. Dietary copper supplements are an attractive idea but probably not of benefit to other than a small subgroup of potential aneurysm formers, which we have currently no way of easily identifying. The only piece of prophylactic advice we can usefully offer at present is one most patients will have heard many times before: to stop smoking

What is the natural history of the disease and can patient selection be improved?

Before surgical repair of aortic aneurysms became established, Estes showed that the 5-year survival rate following diagnosis was only 20 per cent[33]. Even in groups turned down for surgery because of severe intercurrent disease, the cause of death in over a quarter is still rupture of the aneurysm[34,35]. Szilagyi and colleagues demonstrated as long ago as 1966 that the life expectancy after successful repair approached normal[7] and this, together with elective mortality rates of less than 5 per cent in most centres[11], has led to a generally aggressive policy favouring surgery. Reasons commonly put forward for not offering surgery include small aneurysm size, advanced age and medical illness; we would argue that, in many such cases, conservative management is not warranted.

Small aneurysm size is not a justifiable reason for deferring surgery The risk of rupture certainly increases with diameter, as demonstrated by Darling *et al.*[36]. In an autopsy study of 473 patients with unoperated aneurysms, they showed that 60 per cent of aneurysms more than 10 cm in diameter had ruptured, while 45 per cent of those between 7 and 10 cm had done so. However, there was still an appreciable incidence of rupture in the smaller aneurysms a 25 per cent rupture rate in aneurysms between 4 and 7 cm and a 9 5 per cent rate in aneurysms less than 4 cm in diameter. Remembering that there is an 80 per cent overall mortality rate from ruptured aortic aneurysm, this means that approximately one in 12 of unoperated aneurysms less than 4 cm in diameter will cause the death of the patient. Szilagyi *et al.*[34] have also demonstrated that small neurysms are not 'safe' They followed 156 patients with aneurysms of various sizes who had been denied surgery on grounds of unfitness and/or small aneurysm size (which they defined as less than 6 cm) In the 'small' aneurysm group, rupture accounted for 31 per cent of deaths, 39 per cent of these occurring within 2 years of diagnosis Clearly, the figure of 31 per cent would be even higher in a fit population which had been denied surgery on the basis of aneurysm size alone

In Cronenwett's study mentioned above[32], 67 patients with small aneurysms were followed up with serial ultrasound scans for 36 months. The authors confirmed what had previously been reported[37,38]. namely, that small aneurysms increased in transverse diameter by about 5 mm per year, whereas the anteroposterior diameter increased by an average of only 2·2 mm per year. However, the authors found that the initial anteroposterior diameter was a better predictor of eventual rupture than either the transverse diameter or the ratio between the diameters of the aneurysm and the proximal aorta Of the 67 patients, 12 ruptured their aneurysms and eight of these died. Using linear regression techniques, the authors calculate that the presence of a small aneurysm carries a risk of death from rupture of 5 per cent per year Collin[39] has pointed out that, as the death rate from all causes in men aged 60–64 years is 2·2 per cent per year, the presence of a small aneurysm in such a man raises his expected annual death rate by 230 per cent Even in men aged 80–84 years, with a much higher death rate from all causes, the risk of death each year is increased by 38 per cent by the presence of a small aneurysm This seems to us to be strong justification for the elective resection of all small aneurysms, patient fitness permitting.

Mounting evidence also exists that age *per se* is not a reason for withholding surgical treatment. O'Donnell *et al*[40] have reported their experience with 111 octogenarians presenting to their unit with a primary diagnosis of aortic aneurysm over a 15-year period. Thirty patients had ruptured aneurysms and, of these, 23 were operated on Of the 81 patients with non-ruptured aneurysms, 19 had urgent surgery for acute expansion, 44 had elective operations and 18 were not offered surgery on medical grounds (usually severe cardiovascular disease). Thus, the number of patients denied surgery overall was only 25 (22 5 per cent). Of the operated patients with rupture, 74 per cent died, while only 2 per cent (one patient) of those undergoing purely elective surgery died, a rate which, as the authors comment, is comparable to any series of elective aneurysm surgery, irrespective of age. Of the non-operated group, over half had died within 2 years, 59 per cent of the deaths being due to rupture despite the presence of other significant illnesses which had prevented elective surgery. Equally importantly, the authors investigated the quality of life in patients surviving surgery After 1 year, 86 per cent of patients who had undergone elective surgery were judged to be the same as, or better than, before the operation Slightly lower figures were found in the groups having emergency surgery By contrast, less than 40 per cent of non-operated patients had remained as well as before diagnosis, presumably reflecting the progression of their underlying medical conditions.

The authors conclude that most patients aged over 80 years with an aneurysm will do well following elective surgery This is also the conclusion reached by Soreide *et al.*[8], who found a 9 per cent mortality rate attaching to patients undergoing elective aneurysm at the age of 85 years However, details of the selection procedure are not given

Our policy now is to offer elective surgery to all non-obese patients in their eighties who are physically fit and mentally alert, and we would certainly consider surgery in patients even older. General practitioners are perhaps understandably reluctant to refer very old patients with aneurysms[41]; in the light of the disease's natural history and current operative mortality rates, this reluctance would seem to be becoming harder to justify. Certainly, were an 80-year-old man found to have, let us say, a low rectal carcinoma, he would be rapidly referred for consideration of an abdominoperineal resection. Similar urgency should attend the presence of an aneurysm, which has a poor prognosis if untreated but the treatment of which (unlike that of a low rectal carcinoma) is nearly always curative and leads to a good quality of life.

Other factors commonly leading to exclusion from surgery include intercurrent renal, cardiac, malignant and cerebrovascular disease. In a prospective study of 187 patients selected for non-operative treatment, Flanigan *et al.*[42] concluded that current exclusion criteria may be too strict. Although admitting that individual circumstances will, of course, be of prime importance in each case, they specifically recommend that neither stable angina nor a history of myocardial infarction occurring more than 6 months previously should be considered as contraindications to surgery. Similarly, the high level of associated peptic ulcer disease[43,44] should not preclude operation in affected patients; if medical measures fail, a synchronous vagotomy and pyloroplasty has been reported as safe[45].

In summary, the natural prognosis of aortic aneurysm disease is poor. The group of patients to which we should be offering surgery seems likely to expand to include those aged over 80 years, those with stable cardiovascular disease and those with small aneurysms.

Screening: how, who, and at what cost?

If most patients in whom an aneurysm is found fortuitously are offered surgery, it seems logical to look into the feasibility of screening for the disease Simple abdominal palpation is not an adequate method for reliable diagnosis; at least two small-scale screening programmes have confirmed this by comparing ultrasonography findings with physical examination[41,46], while Robicsek has shown that the rates of both false-positive and false-negative results preclude it from consideration as a screening tool[47]. Ultrasound scanning is currently the most practical and accurate way of detecting aneurysms in large numbers of people[48] Most would agree that screening is probably only worthwhile in men, who are affected at least four times more commonly than women[49,50]. Any screening programme will need to be run in conjunction with a vascular surgical unit as many general practitioners will not refer patients with known aneurysms for a surgical opinion[41], although there is evidence that they can be persuaded to do so[51].

If all men in the age group 65–80 years were screened by ultrasound scan, how many aneurysms might one expect to detect? In one of the few pilot studies reported, Collin *et al.* found four aneurysms among 141 men of this age who responded to an invitation to be scanned[52], an incidence of 2·8 per cent, while Scott, scanning 160 people of both sexes in this age group, found an incidence of aortic diameter greater than 3·5 cm of 2 7 per cent[53] Taking into account the operative mortality for elective repair, equipment and staffing costs, the cost of each elective operation performed and the money saved by doing fewer emergency procedures (a ruptured aneurysm costs almost twice as much to treat as an elective one[54]), it has been calculated that each life saved would cost the health service between 6600 and 9000 pounds sterling[55,56]. Both these figures are substantially less than the 15 000 pounds sterling, 'or very likely much more'[57], that it would cost to save a life by mammographic breast cancer screening

If this is considered too expensive, it might be possible to screen high-risk groups Males with hypertension or with peripheral vascular disease are two subgroups which have been the subject of pilot studies. Two studies of men with peripheral vascular disease revealed incidences of aortic aneurysm of 12 per cent[58] and 9·6 per cent[59]. Incidences of 10·7 per cent[60] and 5·3 per cent[49] have been reported in elderly male hypertensives, although a larger Swedish study found only one aneurysm in 245 patients attending a hypertension clinic[61]. In this study, however, both sexes were included, and the upper age limit was set at 70 years, which was perhaps too young for the purpose.

Two other groups worth screening would seem to be first degree relatives of known aneurysm patients[15] and patients with chronic obstructive airways disease. The latter are not known to have a higher incidence of aneurysms, but when they do get one it appears to carry a higher risk of rupture[32].

Are further surgical or medical advances likely in management?

The refinement of surgical techniques in abdominal aortic aneurysm repair has been reviewed by Bergan[62], and further simplification seems unlikely at present. The use of the external pneumatic counter-pressure G-suit (J. C. Peacock and Son Ltd., Newcastle upon Tyne, UK), introduced in the early 1970s as a method of controlling intra-abdominal haemorrhage pre-operatively[63], has not become widespread. The ringed intraluminal graft, involving sutureless anastomoses, may find a role in the management of ruptured aneurysms, especially in the obese and those with very friable aortas[64]. Much of the reduction in mortality rates in recent years is because of improved anaesthesia and (in the case of rupture) resuscitation. Autotransfusion is fast becoming an accepted technique in all branches of surgery involving major blood loss and has been successfully used in aneurysm repair[65]. Its use may be life saving when antibodies cause difficulties with the rapid cross-matching of blood. Further reduction in death rates seems likely to come from increasing the ratio of elective to emergency operations, and this is the desired effect of any screening programme.

Some intriguing work on the correction of low α_1-antitrypsin levels may be relevant to the future medical management of abdominal aortic aneurysms. Wewers *et al.* have found that α_1-antitrypsin levels can be significantly increased in deficient patients by the administration of danazol[66] and to a lesser extent by tamoxifen[67]. These agents act by stimulating the hepatic synthesis and release of α_1-antitrypsin. Although this work was done with the treatment of panacinar emphysema in mind, it raises the concept of reducing the risk of aneurysm rupture by lowering the elastase:α_1-antitrypsin ratio, the balance of which seems to be altered in many aneurysm patients.

The DNA ploidy of breast cancer tissue from paraffin blocks was measured by flow cytometry in 117 patients whose disease had been detected and treated with surgery between 1974 and 1976. Patients with aneuploid tumours had positive axillary nodes and distant metastases more often than those with diploid tumours. Aneuploid tumours were more common in postmenopausal than premenopausal women. The S-phase fraction (SPF) was significantly higher in aneuploid than in diploid tumours and positive axillary lymph nodes were found in 26 per cent of the patients who had a tumour with a SPF below the median (4·8 per cent) and in 48 per cent of those with tumours with SPF values above the median. At the primary clinical investigation 2 per cent of the patients with diploid tumours and 6 per cent of those with aneuploid tumours had distant metastases. During the follow-up, the proportion of patients with distant metastases increased to 42 and 72 per cent, respectively. With a follow-up of 11·5 years, the DNA aneuploidy of the tumour showed a significant association with decreased survival. Thirty-three per cent of patients with diploid and 65 per cent of patients with aneuploid tumours had died from breast cancer during the follow-up ($P<0{\cdot}001$). All patients with hypertetraploid or multiploid tumours died from breast cancer. High SPF values were associated more closely with distant metastases or death during the follow-up than low SPF values. Our results suggest that DNA ploidy measured by flow cytometry from paraffin embedded tissue blocks of human breast cancer can be used to predict the aggressiveness of the tumour and the survival of the patients.

Keywords: Breast cancer, tumour ploidy, survival

Previous reports based on microspectrophotometric measurements of DNA have suggested that the ploidy of the cells in neoplastic tissue from patients with primary breast cancer may be of prognostic value[1,2]. In earlier studies with flow cytometry the association of DNA content with prognosis, remission time, disease free survival, and lymph node involvement has been demonstrated, but the results are not uniform[3–5].

We have undertaken a study to measure the DNA content of paraffin embedded primary breast cancer tissue by flow cytometry, because most of the flow studies have been done with fresh material and the follow-up time has been short. Our series consists of breast cancer patients treated initially by surgery alone from 1974 to 1976 at the Kuopio University Central Hospital.

The aim of this study was to investigate the relationship between tumour ploidy and prospectively recorded prognostic factors in a group of patients whose clinical history was already known. We wanted to study especially the relationship between DNA ploidy and survival in patients with primary breast cancer.

Patients and methods

The original material consisted of 119 women with primary breast cancer treated mainly under the care of one surgeon (P.P.) at the Surgical Department of University Central Hospital of Kuopio, Finland. In two cases the flow cytometry investigation was unsatisfactory and these patients were excluded. Of the remaining patients, 55 had been subjected to a modified radical mastectomy (Patey)[6] in which the major pectoral muscle was preserved but the pectoralis minor muscle removed. Nine patients had been subjected to a modified radical mastectomy in which the pectoral muscles were saved, but the muscle fascias stripped. Simple mastectomy had been performed in 53 patients. All methods included axillary node evacuation. None of the patients received chemotherapy preoperatively. Postoperative radiotherapy was given if the tumour was stage II or a higher stage[7]. For all these patients a series of prognostic factors had been recorded at mastectomy, including the age of the patient, menopausal status, lymph node status, tumour size, presence of distant metastases, and histological classification. The mean follow-up time was 12·4 years (range 11·5–13·3 years).

Patients were classified as premenopausal if they were still menstruating at the time of surgery and under the age of 52 years. Lymph node staging was done at the time of mastectomy using axillary node and fat evacuation, and the node involvement was judged histologically. All lymph nodes were serially sliced to sections which were 4–5 mm thick, embedded in paraffin, sectioned at 5 μm, stained with haematoxylin and eosin, and examined by microscopy for micrometastases. Tumour size was recorded as the maximum diameter measured in the fresh mastectomy specimen. Metastatic lesions were detected by bone and liver radio isotope scan, liver ultrasound, routine laboratory tests reflecting the bone and liver metabolism, and bone and chest radiography. Metastases were verified by surgical biopsy, when possible. Patients with metastases were given hormonal therapy if the tumours were receptor positive.

All patients were followed up in the outpatient department by the same surgeon. In the first 12 months, they were examined every 3 months, then at 6-monthly intervals for 72 months, and annually thereafter. Survival and the time elapsed before recurrence were recorded.

Samples for DNA determination were prepared from paraffin blocks using a modification of the method described by Hedley[8]. Blocks with representative tumour tissue were chosen. From these, two 50-μm-thick sections were cut and deparaffinized. Better nuclear samples are obtained by using 50-μm-thick sections[9] than 30-μm-sections as originally described by Hedley[8]. The pepsin treatment of the deparaffinized sections was replaced by proteinase K (Sigma Chemical Company Ltd., Poole, UK) treatment (30 min at 10 μg/ml) at room temperature, which in our hands gave somewhat improved results. After filtration the nuclei

were treated with 10 μg/ml RNAase and stained with 25 μg/ml ethidium bromide (Sigma Chemical Company Ltd.) for at least 1 h. The DNA was determined by flow cytometry with a FACS IV (Becton Dickinson UK Ltd., Oxford, UK) instrument using the emission at 488 nm at 200 mW. The total emission above 560 nm was recorded. Samples with a coefficient of variation above 8 per cent were rejected. There were two such cases out of 119 in our basic material. As the staining intensity of fixed nuclei varied from one sample to another, no internal standard was included. The lowest peak was given a DNA index value of 1 and the DNA indices of other peaks were calculated with this as a reference. Thus there were no hypodiploid tumours in our material. The S-phase was calculated using the built-in computer program in the FACS IV. Tumours with a DNA index of 1·00–1·049 were recorded as diploid, those with a DNA index of 1·05–1·75 as hyperdiploid, and those with a DNA index of 1·76–2·00 as near tetraploid. The cut off point, 1·75, between these two categories is somewhat low but is based on our experience on the location of the G2 population using our methodology. Tumours with a DNA index >2·0 were considered hypertetraploid. The grouping of cases is shown in *Table 1* and typical peak patterns in *Figure 1*. In this paper we defined aneuploid tumours as tumours with a DNA index outside the diploid range. This definition also includes multiploid tumours.

Statistical analysis was performed at the University of Kuopio using the SPSS-X (SPSS Incorporated, USA) program in a VAX 11/780 (Digital Equipment Corporation, USA) computer. Differences between the groups were analysed by the χ^2 test and *t*-test. Actuarial survival curves were calculated according to the life-table method. Survival was calculated by counting as breast cancer deaths only patients who died with known metastases and censoring for non-cancer deaths. Survival without censoring for non-cancer deaths is referred to as 'crude survival'.

Table 2 *DNA ploidy, age, and menopausal status in 117 patients with breast carcinomas*

DNA ploidy	Mean(s.d.) age (years)	Premenopausal	Postmenopausal	Total
Diploid	55·7 (14·6)	21	24	45
Aneuploid*	60·3 (12·1)	17	55†	72

*Includes hyperdiploid, tetraploid, hypertetraploid, and multiploid tumours; †$P=0·05$ (difference between premenopausal and postmenopausal women)

Results

Of the breast cancers analysed, 45 of 117 (38 per cent) had a diploid DNA index, the remaining 72 tumours (62 per cent) were aneuploid (*Table 1* and *Figure 1*). The diploid tumours were detected in younger patients (mean(s.d.) age 55·7(14·6) years) than the aneuploid tumours (60·3(12·1) years) but the difference was not statistically significant ($P=0·10$). The near tetraploid and hypertetraploid tumours occurred in still older patients (mean (s.d.) age 63·0(12·8) years and 68·1(7·5) years respectively, *Table 2*; $P=0·10$). Of the 117 patients 38 (32 per cent) were premenopausal. The premenopausal patients had about the same number of diploid and aneuploid tumours, but more than twice as many of the postmenopausal patients had aneuploid tumours than had diploid ones. The difference is statistically significant ($P \leqslant 0·05$; *Table 2*).

There was no statistical difference in the size of diploid (mean(s.d.) diameter 3·3(2·3) cm) and aneuploid tumours (3·5(1·8) cm, $P=0·65$).

Lymph node involvement was observed at the time of primary investigation in less than one-third of the patients with diploid tumours (*Table 1*) and in about half of the patients with aneuploid tumours. The difference is statistically significant ($P \leqslant 0·05$). At the time of primary investigation only one patient with a diploid tumour and four patients with aneuploid tumours had distant metastases. During the follow-up there was a substantial incidence of metastases, so that at the end of the study 42 per cent of the patients with diploid tumours, and 72 per cent of the patients with aneuploid tumours had distant metastases (*Table 1*). The difference is statistically highly significant ($P<0·001$). One-third of the patients with diploid cancer and two-thirds of the patients with aneuploid tumours died of their disease (*Table 3*). The difference is statistically highly significant ($P<0·001$).

The S-phase fraction (SPF) of the tumour cells could be determined in 54 cases. The SPF was significantly higher in aneuploid than in diploid cancers. The median of SPF in our material was 4·8 per cent. The means(s.d.) were: diploid tumours 5·9(4·0) per cent; aneuploid tumours 8·3(7·3) per cent. However, the difference is statistically not significant. Tumours

below the median SPF ($n=27$) were smaller (mean diameter 2·7 cm) than tumours above the median SPF ($n=27$; 3·8 cm). The difference is statistically significant ($P=0·05$). A quarter of the patients with tumours where the SPF was below the median and half of those with tumours where the SPF was above the median had lymph node metastases, but the difference was not significant (*Table 4*). As regards distant metastases, there was a correlation with the SPF (*Table 4*), but no difference could be detected in relation to deaths. When 7·0 per cent, rather than the median 4·8 per cent was chosen as the cut off point for SPF, the difference between the groups increased (*Table 5*)

The difference in the 11·5 year survival was statistically significant between patients with diploid and aneuploid tumours when tested by life-table analysis (*Figures 2* and *4*). When 7·0 per cent was chosen as the cut off point for the SPF, the difference between the groups increased considerably (*Figures 3* and *5*). There was little difference between tumours with a SPF of 3·5–7·0 per cent and those with a SPF <3·5 per cent (*Figures 3* and *5*). This was true both for the survival (breast cancer deaths only; *Figure 3*) and for the crude survival (all deaths; *Figure 5*).

Discussion

Flow cytometric DNA analysis is a rapid, objective, and reproducible method for the routine examination of fresh tissue and also of fixed paraffin embedded tissue[10]. In a retrospective study fresh tissue is not available, but paraffin blocks are readily available. In our study such samples were suitable for DNA ploidy analysis, and only two of 119 tumours (2 per cent) had to

be rejected because of poor technical results. It seems that flow cytometry offers a good basis for the development of a diagnostic grading system[11]. Our study was designed to clarify some of the discrepancies which have emerged in studies on DNA flow cytometry of breast cancer, and to explore the potential uses of this method in diagnostic and prognostic grading

Our material was collected, diagnosed, treated and followed up mainly by one surgeon, and therefore the diagnostic criteria and therapeutic decisions are as uniform as possible This eliminates interobserver and interlaboratory variations[12,13], which may greatly decrease the power of an analysis of biological and clinical correlations.

In our material there was a difference in survival between breast cancer patients with diploid and aneuploid tumours after a mean follow-up of 12·4 years. Previously aneuploidy has been reported to correlate with a poor survival[3,4,14] after a follow-up of 2·8–7·7 years. However, another study, where the follow-up time was 7·7 years, failed to show a difference in survival between diploid and aneuploid tumours[5]. Our present results support the former findings. Our follow-up time seems to be one of the longest reported in the literature.

Published reports give conflicting results about the correlation between tumour size and tumour ploidy Some reports like our present one fail to show a statistically significant difference[14–16]. Though in many of these studies the aneuploid tumours have been somewhat bigger. In those studies where a significant difference has been found the aneuploid tumours have always been bigger than diploid ones[4,5,17]. The larger size of the tumour correlates with the age of the tumour and its growth rate. Direct measurements of tumour doubling time in human breast cancer cannot easily be done and requires fresh tissue. An estimate can be made by studying the mitotic rate by normal light microscopy[18,19] or the SPF by flow cytometry. Both of these methods give results which correlate with patient survival. In our study, tumours with SPF below the median were smaller than those above the median. On average, the proliferation rate in small tumours (usually diploid) is lower than in large tumours (usually aneuploid).

Aneuploid tumours showed a statistically significant association with the presence of axillary lymph node metastases Earlier studies have failed to demonstrate such an association[5,14–16], but again, even though statistically significant differences have not been detected, aneuploid tumours have generally been associated with a higher number of cases with positive axillary lymph nodes. In the present study aneuploid tumours showed a significant association with distant metastases. Earlier reports have been conflicting[5,14,15]. In the present study distant metastases were more common in patients with aneuploid tumours at the time of primary surgery, and during the follow-up, patients with aneuploid tumours developed distant metastases more often than those with diploid tumours.

Breast cancer patients with tumours below the median SPF value had significantly fewer distant metastases than those with tumours above the median. Kallioniemi *et al.*[15] also found this association. The finding suggests that activated cell kinetics and distant metastases are associated. Baak *et al.*[18] have demonstrated that the mitotic activity index is the most prominent prognostic parameter in the histology of breast carcinoma. Our Finnish study[19] also showed that mitotic activity index is important, although not to the same extent as in the study from The Netherlands[18]. Mitotic index and SPF do not measure the same parameters. The mitotic index varies in different parts of the tumour and is therefore measured where the mitotic activity is highest, at the periphery. In flow cytometry no distinction is usually made between the centre and periphery of the tumour. Because of this, there is a considerable sampling variation, which may affect the results. It has been shown that when multiple samples are taken from the same tumour there is some variation in the DNA index and a much greater variation in the SPF[20]. The biological importance of the SPF is demonstrated by the fact that there is a statistically significant difference in survival between patients with a SPF above and below 7·0 per cent.

In women over the age of 35 years, an accurate diagnosis of breast cancer can be made in over 95 per cent of patients using a 'triple assessment' system collating information from clinical examination, mammography, sonomammography, and fine-needle aspiration cytology. These methods have not been specifically evaluated in women aged 35 years or less, hence a study was undertaken on 30 such patients. Clinical examination was unreliable in predicting malignancy with a sensitivity of only 37 per cent. Thirty per cent of patients presented with a lump which had the clinical features of a fibroadenoma. Radiological methods were less sensitive in detecting malignancy in this age group than in older patients. The sensitivity of aspiration cytology was 78 per cent which was higher than that for breast cancer at all ages. Histology showed that there were fewer low grade tumours and fewer scirrhous tumours in this age group than in a control group of women aged over 35 years. This study indicates that cytological confirmation of apparently benign focal breast lesions in young women is essential, especially when these are managed conservatively.

Keywords: Breast cancer, cytology

The diagnosis of breast cancer in young women is unexpected and alarming to both patient and clinician. In women over the age of 35 years an accurate diagnosis of malignancy without histology can be made in over 95 per cent using a 'triple assessment' system collating information from clinical examination, X-ray mammography and aspiration cytology[1-4]. If ultrasound mammography is added the diagnostic sensitivity is further enhanced[5]. These methods have not been specifically evaluated in women aged 35 years or less. It is in this age group that the nature of palpable breast lesions must be established if apparently benign lumps, particularly fibroadenomas, are to be managed conservatively as recently advocated[6,7].

A study was undertaken to assess the diagnostic sensitivity of clinical examination, X-ray mammography, ultrasound mammography, and aspiration cytology, used alone and in combination, in women between 19 and 35 years of age with primary breast cancer.

Patients and methods

All patients under 36 years of age who presented to the Southampton Breast Clinic with a palpable mass between January 1980 and March 1988 and who were found to have breast cancer were studied and analysed retrospectively

All patients were investigated by clinical examination and the majority had X-ray mammography, ultrasound mammography, and aspiration cytology. Each modality was assessed on a five-point scale, previously developed in Southampton[4] (−2, definitely benign; −1, probably benign; 0, inconclusive, +1, probably malignant; +2, definitely malignant) and an overall score obtained. Patients with scores between −6 and −1 were treated by excision biopsy, scores between 0 and +3 required Trucut® biopsy (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) or occasionally frozen section, and scores between +4 and +6 were treated by definitive surgery provided cytology had a positive score.

Histology was available on all pateints. A control group of 30 consecutive patients aged over 35 years was taken from women with operable carcinomas attending the breast unit during the same time period. Bloom's grading was ascribed to each tumour as was the degree of fibrous stroma (see below).

The scoring system allows an objective comparison of the diagnostic sensitivity of each method in detecting malignancy Each patient was examined in the breast clinic by either a consultant or a senior registrar A Phillips 7100 Static B® scanner (Phillips, Eindhoven, The Netherlands) was used for the ultrasound examination; a 7 5 MHz transducer was applied directly to the skin, scanning at 2-mm intervals over the breast mass The investigation was performed and interpreted by one of two radiologists with an interest in breast disease X-ray mammography was performed using a Senograph® (CGR Senographic, Paris, France) X-ray set with Kodak Min-R® (Hemel Hempstead, UK) film, standard craniocaudal and lateral oblique views were taken

Aspiration cytology was performed with a 21 gauge needle and disposable syringe mounted on a syringe holder. Suction was applied as the needle was introduced into the lesion several times The contents of the syringe were then expressed on to slides, half of which were immediately air dried and the remainder fixed in acid-alcohol

Results

There were 30 patients (median age 31 years. range 19–35 years); the duration of symptoms was from 3 weeks to 6 months, with a mean of 9 weeks. One patient was pregnant and two were lactating.

Eighteen patients presented with a painless lump, in ten the lump was painful, and in two pain was the only presenting feature, although at examination a lump was palpable. Eleven lumps (37 per cent) were clinically malignant (scores +1 or +2) and six lumps were of indeterminate nature (zero score), giving a total of 57 per cent with some suspicion of malignancy. Thirteen (43 per cent) were considered benign (nine clinical fibroadenoma, four benign breast change).

X-ray mammography was performed on 22 patients (*Table 1*), this showed evidence of malignancy (+1 or +2 scores) in 12 (55 per cent), and was indeterminate (0 score), mainly due to breast density, in five, together giving an X-ray suspicion of malignancy in 77 per cent. A benign diagnosis was made in five (23 per cent) due to well-defined masses in four patients, and severe glandular density obscuring one tumour.

Twenty-six patients underwent sonomammography This showed evidence of malignancy in 15 (58 per cent) and was inconclusive in a further three tumours, resulting in a suspicion of malignancy in 69 per cent. Eight tumours were diagnosed benign initially (six fibroadenoma, two fibrocystic change),

Values in parentheses are 95 per cent confidence intervals

when reviewed retrospectively the impression was changed in five to indicate malignancy; three of these occurred during the very early experience of breast ultrasound.

As described in previous papers[4,8–10] the scoring system for cytology defines an obvious malignant aspiration as +2, reserving +1 for well differentiated carcinomas and poorly cellular malignant aspirates. Zero scores are equivocal and therefore suspicious of malignancy; +2 and +1 scores are regarded as positive. Cytology showed malignancy in 21 of 27 patients (78 per cent), it was equivocal in four other patients, increasing the suspicion of malignancy to 93 per cent. There were two false negative results. In addition there were three cellular aspirates which when repeated proved positive in one and equivocal in one.

As the investigations were added to the clinical diagnosis, sensitivity for carcinoma rose from 54 per cent for those undergoing clinical examination and sonomammography to 71 per cent for those undergoing clinical and X-ray examination; when these three procedures were combined, the sensitivity was 75 per cent for carcinoma. Clinical examination with fine-needle aspiration gave a 90 per cent sensitivity, and, when imaging was added to these, 95 per cent of all cancers were recognized preoperatively. In two patients, malignancy was not positively identified by any method (neither had X-ray mammography, however); in both cases the lesion was thought to be a discrete area of benign breast change. The lesions in the two patients who did not have aspiration cytology were clinically and radiologically considered to be fibroadenoma (*Table 1*).

Aspiration cytology correctly identified six cases as malignant, when other modalities gave inconclusive or benign results. Similarly, three carcinomas were correctly identified by X-ray mammography and by ultrasound when aspiration cytology was inconclusive.

Most of the carcinomas were ductal in origin (*Table 2*). Four of these were predominantly *in situ* and one was entirely *in situ*. These five could not be ascribed a Bloom's grade.

Twenty-five invasive carcinomas were compared with a control group of 30 carcinomas from women aged over 35 years by ascribing a Bloom's grade to the tumours and assessing the degree of fibrous stroma on a three-point score. The two groups were combined and read 'blind' on two occasions by one observer (A.H.). The two readings gave 87 per cent correlation, where the observations disagreed, a third deciding reading was made which in most instances agreed with the second reading. There was a significantly smaller proportion of low grade (Bloom's grade I) and densely scirrhous tumours in the carcinomas in young women than in controls (*Table 3*).

Discussion

Breast cancer in women below the age of 35 years is uncommon, and a diagnosis needs a high index of suspicion, as shown by the delay in reaching a diagnosis in some of these patients; a similar observation has been recorded previously[6].

The value of combined clinical examination, imaging and fine-needle aspiration cytology in breast cancer diagnosis is well established[1–5]. However, these studies have largely been conducted with women over 35 years of age in whom each method has a high sensitivity for malignancy and, when used in conjunction, provide an accurate preoperative diagnosis in up to 99 per cent of patients with breast cancer[5].

In women aged under 35 years, clinical examination, mammography and ultrasound were less accurate than in older patients. Clinical examination diagnosed cancer in only 11 (37 per cent) patients and was suspicious in a further six (total 57 per cent), compared with the 85 per cent total sensitivity in older patients. Nine patients (30 per cent) presented with a lump which had the clinical features of a fibroadenoma (i.e. small, discrete, solid and mobile). X-ray mammography showed an overall sensitivity of 77 per cent compared with 93 per cent recorded previously in older patients; this is attributable to greater breast density in younger patients and to good border definition of some cancers. Sonomammography indicated carcinoma in only 69 per cent, although it identified lesions in

Table 3 *Bloom's grade and fibrous stroma compared in women aged 35 years or less and women over 35 years*

	Bloom's grade				Fibrous stroma			
	I	II	III	Total	+	++	+++	Total
Women 35 years or less	2	11	12	25	7	17	1	25
Controls (over 35 years)	16	7	7	30	4	17	9	30
Total	18	18	19	55	11	34	10	55

the other patients, labelling them benign. Five of these eight false negative results occurred in the early stages following the introduction of breast ultrasound[11]; when reviewed, greater experience identified malignant features in three, which would have increased the sensitivity (positive and suspicious lesions) to 80 per cent However, in our hands the sensitivity of ultrasound for carcinoma is now of the order of 93 per cent, but there remains an overlap between fibroadenoma and circumscribed carcinoma which is particularly relevant to younger patients in whom fibroadenoma is more common.

Fine-needle aspiration cytology was the best single investigation in this series, with an indication of malignancy in 93 per cent of patients and a specificity of 100 per cent, the latter being in accordance with our previous reports when adequate smears were obtained[4,5,11].

The cytological sensitivity in this series was higher than previously reported for women of all ages[10], but the difference was not statistically significant. Review of the five cytology reports scored as +1 showed that there was a tendency to reduce the score because of the patients' age: none were particularly well differentiated or poorly cellular which are the reasons for ascribing a +1 score to a positive aspirate. Similarly, review of the four aspirates that were scored 0 reveals two which were consistent with carcinoma on review, reflecting a reluctance to give a positive report. The percentage equivocal was 13 per cent compared with 3·8 per cent for all ages[10]; the difference is statistically significant.

The good fine-needle cytology results may be due to the fact that so few tumours were well differentiated or densely scirrhous. Although there is a wide difference in Bloom's grades ascribed to tumours by different authors, considerable consistency can be achieved both within and between observers[13]. Good consistency of observations (87 per cent) has validated the difference between the two groups of tumours in this study. This finding agrees with Brightmore *et al.*[14] who found an increased proportion of high grade tumours in young women and with Charleston and Feinstein[15] who found evidence for a more rapid growth rate in tumours from premenopausal women.

CA15-3: its relationship to clinical stage and progression to metastatic disease in breast cancer

There is increasing interest in the potential role of monoclonal antibodies as tumour markers in the early detection of metastatic disease. CA15-3 is a circulating antigen which is relatively specific for breast tissue and defined by two monoclonal antibodies. It is elevated in the serum of patients with breast cancer but its relationship to clinical stage and tumour progression has not been well defined. CA15-3 levels have been measured in a consecutive series of 97 patients with breast cancer at the time of diagnosis and at 3-monthly intervals thereafter. All patients have been evaluated and followed by using routine biochemical and radiological parameters to detect occult metastatic disease. There was no difference between a control group of patients who presented with benign disease ($n=18$: *mean(s.d.) 18·0(5·1) units/ml): and those who presented with stage I disease* ($n=37$: *18·4(5·3) units/ml) or stage II disease* ($n=21$: *18·0(4·0) units/ml). Patients with stage III disease* ($n=23$: *32·0(10·4) units/ml) had significantly elevated levels of CA15-3 compared with those in stage I* ($P<0{\cdot}001$). *All patients with documented metastatic disease at presentation or at follow-up had markedly elevated CA15-3 levels* ($n=10$: *155·8(50·2) units/ml). CA15-3 is a reliable tumour marker in patients with advanced disease.*

Despite the widely accepted use of tumour markers such as carcinoembryonic antigen as a means of early detection of metastatic disease in colorectal cancer there has to date been no satisfactory tumour marker for breast cancer which is the commonest malignancy in females. Detection of metastatic disease from breast cancer is presently dependent on clinical examination, non-specific biochemical serum analysis and radiographic techniques. Recent advances in the detection of tumour-specific monoclonal antibodies have made available potential markers for metastatic disease. CA15-3 is a circulating antigen expressed by human breast tissue and is defined by two monoclonal antibodies: DF3, which is found on the surface of mammary carcinoma cells, and 115D8 which is found on milk-fat globule membrane[1,2]. It is relatively specific for breast cancer but its precise role has not been firmly established[3]. This study was prospectively undertaken to define the correlation between the level of CA15-3 and clinical stage of disease in order to determine what part this tumour marker has to play in the follow-up of patients with breast cancer.

Patients and methods

Since October 1986 all patients who presented to the breast clinic at University College Hospital, Galway with carcinoma of the breast were entered into the study. Serum levels of CA15-3 were taken from 18 patients who had benign breast disease in order to determine a normal reference value for this laboratory (mean(s.d), 18 0(5·1) units/ml). Measurements were taken using a commercially available radioimmunoassay kit (ELSA CA15-3, International CIS, Saint Quentin, France) employing a solid phase two-site immunoradiometric assay. Briefly, 25 μl of the patients blood is incubated in a test tube containing the antibody 115D8 coated in solid phase for 1 h at 37°C. The tube is washed and the tracer antibody DF3, labelled with radioactive iodine, is then added The tube is again incubated at 37°C for 1 h After washing, the bound radioactivity is measured using a γ counter CA15-3 levels are then measured from a standard curve, coefficients of variation of the assay are ±8 per cent.

Ninety-seven patients with breast cancer were entered in the study: 35 were premenopausal and 62 were perimenopausal or postmenopausal. The average age was 54 years (range 24–89 years)

The patients were staged according to the standard UICC (International Union against Cancer) breast cancer classification. At presentation 37 patients were in stage I, 21 were in stage II, 23 were in stage III and five were in stage IV Eleven patients presented with disease progression having had definitive surgery for breast cancer before the study period: eight of these had local recurrence confined to the chest wall and three had disseminated metastatic disease.

CA15-3 levels were measured at presentation in all patients and again at 1 month postoperatively. Patients were followed up at 3 months postoperatively and subsequently at 3-monthly intervals.

All patients were screened for metastatic disease with chest radiographs, liver function tests and bone scan at first presentation. Whenever there was a clinical suspicion of metastatic disease at follow-up the screening tests were repeated

Levels of CA15-3 in different stages of disease were compared with levels in patients with stage I disease by analysis of variance. Serial CA15-3 levels at follow-up in all groups were compared with preoperative levels. Statistical significance was taken at the $P<0\ 05$ level

Results

There was no difference between the levels of CA15-3 in those with benign lesions of the breast (mean (s.d.), 18.0(5·1) units/ml) and patients with stage I (18·4(5·3) units/ml) or stage II (18·0(4·0) units/ml) cancer or locally recurrent disease (23·0(8 0) units/ml; *Table 1*). Patients with stage III or IV disease had significantly elevated levels of CA15-3 compared with either the control group or those with stage I disease ($P<0{\cdot}001$). Only 4 per cent of patients with stage I or II disease demonstrated levels of CA15-3 greater than 25 units/ml in this study and no patient in these groups had a preoperative level greater than 30 units/ml. Eighty-three per cent of patients with stage III disease had preoperative levels of CA15-3 greater than 25 units/ml.

A comparison between preoperative CA15-3 levels in patients with stage III disease and postoperative levels at 3, 6 and 12 months demonstrated a progressive decrease which was statistically significant (*Figure 1*).

At presentation five patients had stage IV disease and three others presented with metastatic disease having been diagnosed and treated before the study period. Two additional patients have progressed to metastatic bone disease which was confirmed on bone scan in the course of the study. One of these had stage II disease at presentation (CA15-3 level: 17·0 units/ml) and the other was in stage III at presentation (CA15-3 level: 28·5 units/ml). Both patients have demonstrated elevated levels

of CA15-3 on follow-up and one had a markedly elevated CA15-3 level (113·5 units/ml) at a time when, although she complained of bone pain, her bone scan was negative. Repeat bone scan 3 months later confirmed the presence of metastases (*Figure 2*). No patient with distant metastases had a level of CA15-3 below 50 units/ml and in over 85 per cent of this group the levels were greater than 150 units/ml.

Discussion

Serum CA15-3 levels have been determined previously in healthy controls[4] and in those with carcinomas of other organs and elevated levels have been shown to be relatively specific for breast cancer. Previous studies have confirmed that the levels of CA15-3 are not affected by the age of the patient[4]. The levels among patients with benign disease and stage I and II disease correlate well with the results from other laboratories[3,4]. Several circulating antigens are elevated in association with breast cancer[5–8], but none of these have gained widespread use. Carcinoembryonic antigen has been shown to correlate with change in breast disease status[9] but it is not specific unless patients have hepatic metastases[10]. It has previously been demonstrated that CA15-3 is significantly more sensitive than carcinoembryonic antigen in the evaluation of patients with both primary and metastatic breast cancer[3].

In this study CA15-3 levels correlated with the stage of disease. CA15-3 was not elevated in benign breast disease or stage I or II disease and is not of any value in the detection of early or occult breast cancer. The progressive reduction in CA15-3 levels postoperatively in stage III disease may reflect the decrease in tumour burden. The fact that the decrease is not significant until 3 months after operation may reflect the long half-life of the antigen, the excretory kinetics of which have not yet been established. Moreover, in patients with metastatic disease all of the levels were markedly elevated while those in patients with locally recurrent disease were not, again suggesting that this marker reflects tumour burden. At follow-up the patients with metastatic disease showed neither a clinical response nor a drop in serial CA15-3 estimations

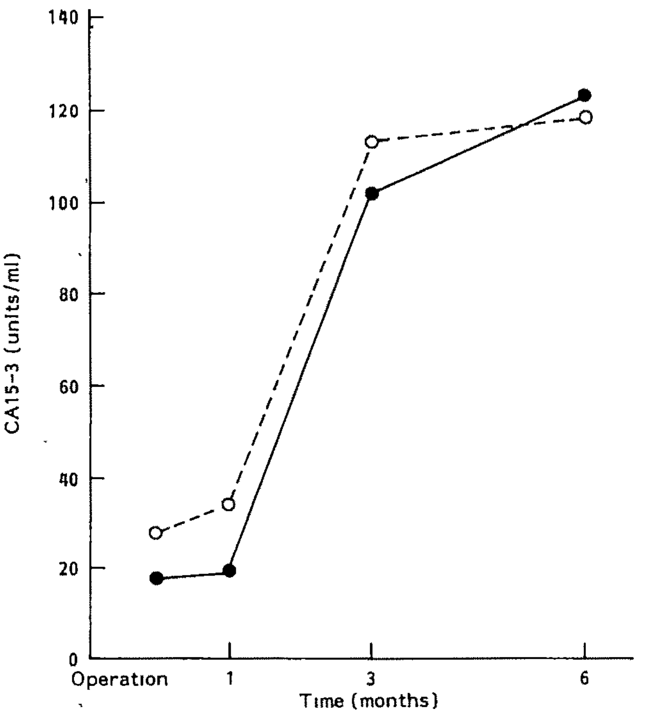

Figure 2 *Serial CA15-3 levels in two patients who developed metastatic disease to bone: +ve, bone scan positive in this patient, −ve, bone scan negative in this patient*

In the future, serial CA15-3 estimations may be used to detect metastatic disease earlier than currently available methods, as occurred in one case in our series. The analysis is simple, more practical and much less expensive than currently available methods.

Additional value of fine-needle aspiration biopsy in a mammographic screening trial

J. Frisell, G. Eklund‡, R. Nilsson†, L. Hellström* and A. Somell

*Departments of Surgery, *Radiology and †Pathology, Södersjukhuset, and ‡Department of Cancer Epidemiology, Karolinska University Hospital, Stockholm, Sweden*

Correspondence to: Dr J. Frisell, Department of Surgery, Sodersjukhuset, S-100 64 Stockholm, Sweden

The Stockholm breast cancer screening trial used single-view mammography as the sole screening method. A majority (63 per cent) of the mammographic selected cases from the first two screening rounds had uncertain mammograms, coded as 3 on an ordinal scale from 1 to 5, where 1 and 2 are dismissed as normal mammograms and 5 stands for a typical cancer. In this group of uncertain mammograms 30 cases were malignant and 431 were non-malignant. The aim of this study was to examine whether surgical biopsy in this group could be replaced by fine-needle aspiration (FNA) biopsy, combined with the information from the mammogram and clinical examination, and whether this diagnostic strategy could select the malignant cases with a high sensitivity. FNA biopsy selected 25 of the 30 mammary carcinomas as definite malignancy or atypia, with a sensitivity of 83 per cent (95 per cent confidence interval: 69–96 per cent), and combined with the information from the mammogram and clinical examination 29 of the malignancies were selected with a sensitivity of 97 per cent (95 per cent confidence interval: 83–100 per cent). In 398 of 431 non-malignant cases the diagnosis was established with the triple diagnostic approach without needing a surgical biopsy. In a clinical follow-up study, up to 64 months after the first screening round, only one false negative case was found, included in the group of 30 malignancies described above. With this strategy the rate of negative surgical biopsies was reduced by 90 per cent in the group with uncertain mammograms and without considerably impairing the reliability of the results.

Keywords: Breast biopsy, mammography, screening, fine-needle aspiration biopsy

If mammographic screening for early detection of breast cancer is to result in the intended decrease in mortality rates, the quality of the screening mammography and the clinical investigations need to be high, otherwise a large number of unnecessary open surgical biopsies will be performed at great cost and with anxiety among the selected women[1–3]. Quality control is particularly important when nationwide screening projects are planned, based on results from the early randomized trials in the USA, The Netherlands and Sweden[4–13].

In screening programmes there is always a large group of selected women whose mammographic findings are uncertain. There is not enough evidence to justify surgery but the mammogram is not normal. Without unlimited resources, these women either have to be submitted to surgery or classified as normal without surgical biopsy and without a time-consuming clinical follow-up.

The Stockholm screening trial began in 1981 and included 60000 women aged 40–64 years. Single-view mammography was the only screening method used and the selected cases were recalled for complete mammography. The mammograms were classified on an ordinal scale from 1 to 5, where 1 indicates a normal mammogram and 5 a typical cancer. Women with codes 1 and 2 have usually been dismissed as normal, while those with codes 4 and 5 have had a surgical biopsy. In the first and second screening rounds 67 and 56 per cent respectively of the selected cases with a complete mammography were classified as code 3 Together with the women with codes 4 and 5 they were recalled for clinical investigation and fine-needle aspiration biopsy (FNA).

The aim of this study was to evaluate the ability of FNA biopsy to detect the small number of malignant cases in the large group of screening-selected women with small pathological mammographic findings. A secondary aim was to determine whether FNA biopsy together with clinical examination and complementary mammography are reliable enough to assure the selected women that their mammographic finding is non-malignant, without support from a negative surgical biopsy.

Patients and methods

Screening programme

A mammographic screening programme was begun in 1981 in south-east Stockholm The population comprised 60000 women aged 40–64 years, of whom 40000 were offered mammography and 20000 functioned as a control group The project and the first round results have been described in detail[14]. The screening was done with an oblique, single-view mammographic projection according to Lundgren and Jakobsson[15]. Participation rates exceeded 80 per cent in both the first and the second screening, with small differences between age groups. The incidence of recalls for further examinations, with results from the first two screening rounds, are given in *Table 1*.

Patients

This study comprises 727 women, selected from the first two screening rounds in the Stockholm screening project Further investigation led to the diagnosis of 223 cancers and 504 non-malignant cases. Of the 504 non-malignant tumours, 398 were classified with FNA biopsy, clinical palpation and mammography, without needing a diagnostic surgical biopsy. Of the 223 mammary carcinomas, 194 cases (87 per cent) were selected with codes 4 or 5, and 29 cases with code 3 at mammography.

Methods

Mammography. A single oblique view by the Lundgren technique was used for screening[15]. If malignancy was suspected the patient was subjected to a conventional three-view mammogram, as stated previously. The complete mammogram was classified, depending on the suspicion of malignancy, from 1 to 5 where 1 and 2 represent a benign lesion, 3 represents a middle group, 4 represents a high suspicion of malignant lesion, and 5 represents a typical cancer.

Triple diagnostic procedure. All selected cases from the screening programme were remitted preoperatively for triple diagnostic procedure, including clinical investigation, FNA biopsy and complementary X-ray, in order to classify the tumour as malignant or non-malignant.

Tumour sampling. FNA biopsy was performed for the cytological diagnosis[16]. A stereotaxic device was used if the tumour was not palpable[17,18]. If the aspirated material was not conclusive, the tumour was excised under general anaesthesia after preoperative localization, carried out in collaboration with the responsible radiologist and guided by the mammogram. The position of the lesion was indicated on the breast with waterproof ink, in accordance with its position on the craniocaudal and lateromedial projections on the mammogram. The surgical specimen was radiographed peroperatively to ensure that the mammographically suspected lesion had been removed[19,20]. The tumour was indicated with a needle to guide the pathologist[19,20]. In some cases, if the aspirated material from the FNA biopsy was not conclusive, and the suspicion of malignancy in the screening-detected lesion was very low, the patient was followed clinically with a new mammogram and sometimes with a new FNA biopsy without a diagnostic surgical biopsy. If the diagnosis of carcinoma was established cytologically, the operation was performed without further diagnostic procedures.

False negative cases. All cases classifed as non-malignant tumour after the triple diagnostic procedure were followed up in the regional cancer registry of Stockholm county; the mean follow-up time was 64 months (median 63 months) after the first screening round and 37 months (median 38 months) after the second round (*Figure 1*). Almost all breast cancers in the Stockholm area are reported to the regional cancer registry.

Results

In the first two screening rounds 728 women (482 in the first round, 246 in the second) were selected and recalled for triple diagnostic procedure (*Table 1*). One case in the first screening round refused further investigations.

The group of mammographically highly suspected lesions (codes 4 and 5) totalled 266 cases: in 194 of these the tumour was malignant and in 72 it was non-malignant. The figures for the first and second screening rounds are given in *Figure 2*. In 79 per cent (141 of 178) of the malignant lesions a preoperative

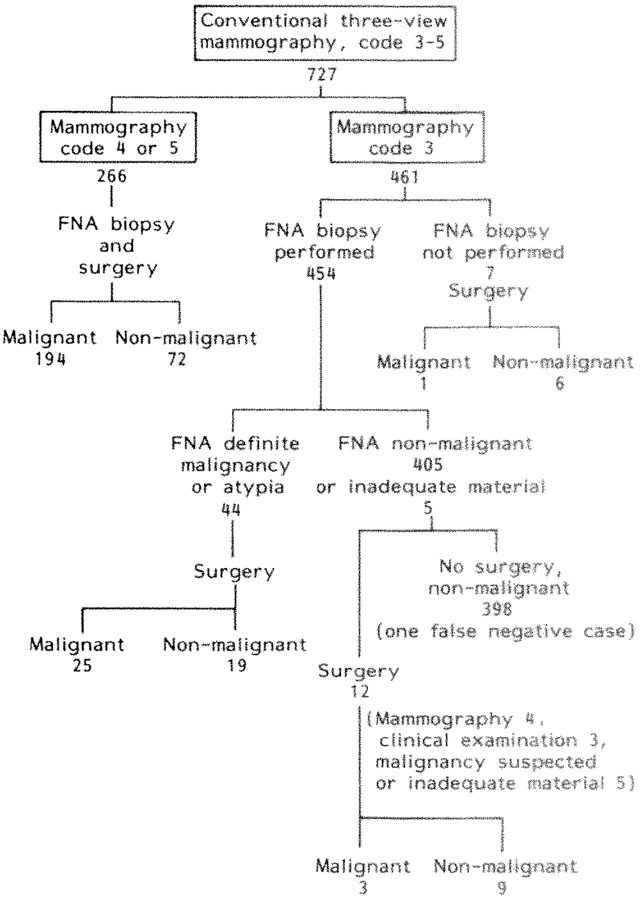

Figure 2 *Comparative flow scheme of the diagnostic procedure in the first and second screening round, in relation to mammography code. FNA, fine-needle aspiration*

FNA biopsy classified the cytology as cancer or suspected cancer. In 16 cases of malignancy the diagnosis was established with surgical biopsy without a preoperative FNA biopsy. Surgery was performed in all but seven of the cases with mammography codes 4 and 5.

The group of mammographically less suspicious lesions (code 3) totalled 461 cases from the first two screening rounds. In 30 cases the tumour was malignant and in 431 it was non-malignant (*Figure 2*). During a clinical follow-up one of the non-malignant cases turned out to be a mammary carcinoma, described below (*Figure 3*). FNA biopsy selected 25 of the malignant lesions, with a sensitivity of 83 per cent (95 per cent confidence interval: 69–96 per cent). In three cases FNA biopsy was negative, and in the fourth case FNA biopsy was not performed. The malignant diagnosis in these four cases was established with a diagnostic biopsy, as the mammogram indicated a suspected malignant lesion. With the triple diagnostic approach, 29 of the malignancies were selected with a sensitivity of 97 per cent (95 per cent confidence interval: 83–100 per cent). In 398 cases the non-malignant diagnosis was established with FNA biopsy together with clinical investigations and complementary mammography, without a diagnostic surgical biopsy. In a clinical follow-up study with mean follow-up times of 64 and 37 months after the first and second screening rounds respectively, one genuine false negative case was found. The women have passed none, one or two further screening rounds after the detection of the non-malignant lesion (*Figure 1*). The false negative case turned out to be a non-invasive intraductal cancer, at the following screening mammography 24 months later (*Figure 3*).

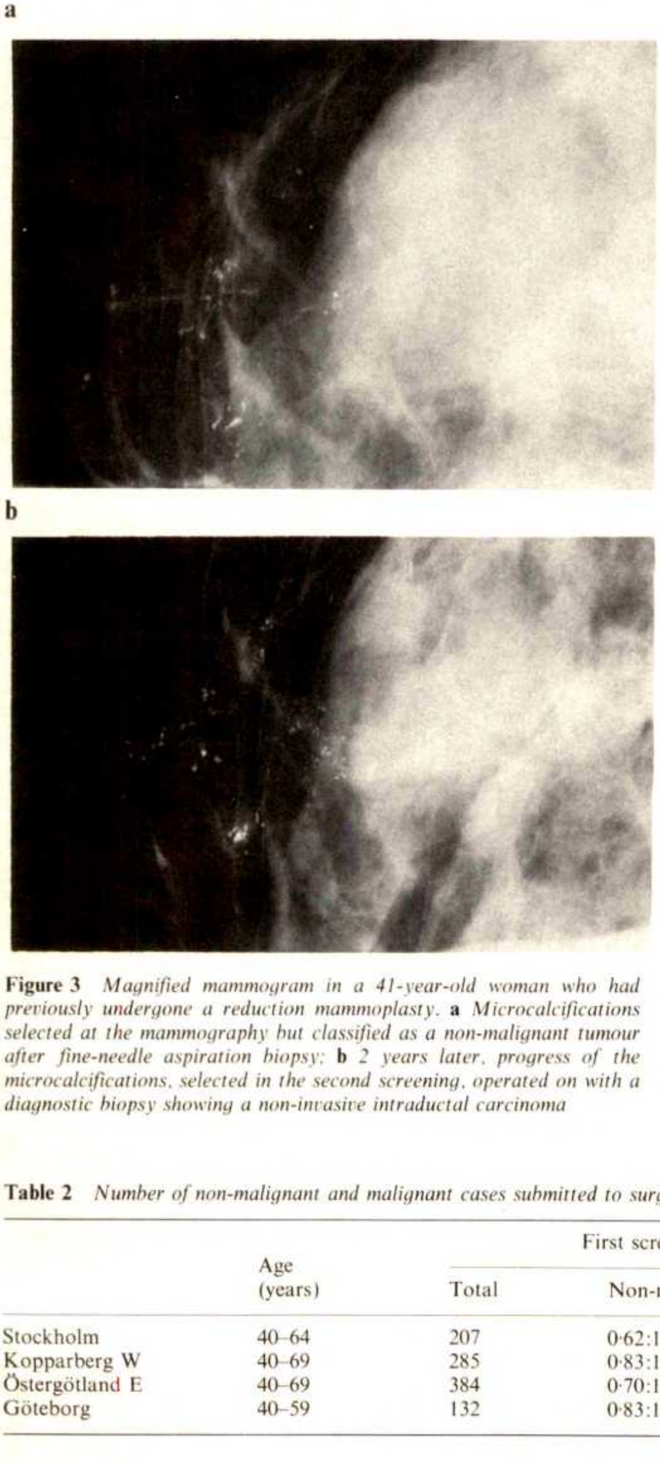

Figure 3 *Magnified mammogram in a 41-year-old woman who had previously undergone a reduction mammoplasty.* **a** *Microcalcifications selected at the mammography but classified as a non-malignant tumour after fine-needle aspiration biopsy;* **b** *2 years later, progress of the microcalcifications, selected in the second screening, operated on with a diagnostic biopsy showing a non-invasive intraductal carcinoma*

The cancer risk in this group of screening-selected women with a classified non-malignant tumour after the triple diagnostic procedure is calculated to be 1·08 (128/32 555 × 274) in the first screening round and 0·40 (95/30 765 × 129) in the second round. The calculated breast cancer risk in this group is 1·5 cancers per woman or 0·75 of a cancer per breast (not significantly different). Two more cancer cases were found in this group but these new cancers emanated from another part of the breast, clearly distinguished from the earlier detected non-malignant lesion.

Table 2 gives the ratio of non-malignant:malignant cases submitted to surgery in four Swedish trials. The rate of non-malignant lesions is falling in the screening rounds that follow the prevalence screening. One reason for this is that many of the benign lesions are selected in the first round. Another is that the radiologist has an earlier mammogram for comparison in subsequent screening rounds.

Discussion

A high proportion of women, 73 per cent and 61 per cent of those selected in the first and second screening rounds respectively, and submitted to the triple diagnostic procedure after complete mammography, had a non-malignant disease. This is in good agreement with the results from the Swedish two-county Study (WE-trial)[21,22].

A high rate of negative biopsies has been reported from North America, with a non-malignant:malignant ratio of 6:1 at biopsy in the Breast Cancer Detection Demonstration Project (BCDDP)[1].

It is desirable that the majority of the non-malignant lesions can be classified as normal not only without diagnostic surgery, but also without an increased number of cases that turn out to be false negative.

In all Swedish screening trials FNA biopsy is frequently used in the triple diagnostic procedure for all selected cases. FNA biopsy was performed in all but a few cases in the Stockholm trial.

Of the screening-selected cases with highly suspicious mammograms (codes 4 or 5), almost all were submitted to surgery, even if the cytology was negative. In this group a preoperative FNA biopsy selected 79 per cent of the malignant tumours in the first two screening rounds as definite or highly suspected cancers. The advantage of a definitive preoperative cancer cytology result in this group is that cancer surgery can be performed from the beginning of the operation, without requiring diagnostic procedures such as frozen section analysis or a two-stage operation.

In the other group of selected mammograms (code 3) there

Table 2 *Number of non-malignant and malignant cases submitted to surgery in the first two screening rounds in four Swedish trials*

	Age (years)	First screening		Second screening	
		Total	Non-malignant:malignant	Total	Non-malignant:malignant
Stockholm	40–64	207	0·62:1	122	0·28:1
Kopparberg W	40–69	285	0·83:1	151	0·50:1
Östergötland E	40–69	384	0·70:1	141	0·33:1
Göteborg	40–59	132	0·83:1	49	0·48:1

were 461 cases; FNA biopsy, together with the information from mammography and clinical examination could be most valuable. With use of the triple diagnostic procedure 29 of 30 mammary carcinomas were diagnosed and FNA biopsy alone selected 25 tumours with definite or suspected malignancy with a sensitivity of 83 per cent

In nearly half (46 per cent) of the 30 mammary carcinomas, the mammographic findings consisted in cases of microcalcifications, most of which were non-palpable. This mammographic feature is commonly associated with malignancy[23]. A liberal attitude towards surgical biopsies in cases of selected microcalcifications on the mammogram, despite a negative cytology result, is recommended.

At the clinical follow-up only one false negative case could be detected (*Figure 3*) This case, with microcalcification on the mammogram, was classified as a non-malignant tumour at the first screening, but was diagnosed as a non-invasive mammary carcinoma 2 years later in the following screening round. Follow-up of the non-malignant cases diagnosed with triple diagnostic procedure, without surgical intervention, could be an important feedback on the effectiveness of the diagnostic methods used in a screening programme.

Full evaluation of a breast cancer screening programme should take into account the undue anxiety generated in the selected women with non-malignant lesions and the psychological harm of having to undergo negative surgical biopsies[1–3].

Table 2 gives the ratio of non-malignant:malignant cases submitted to surgery in four Swedish trials. In all trials in Sweden, the two trials in The Netherlands and the Guildford (UK) trial, the rate of 'unnecessary' surgical biopsies is reported to be low[21,22,24,25], in contrast to the figures from North America and a few additional centres in the UK[1,26,27].

In the Stockholm trial the rate of unnecessary surgical biopsies among selected cases with code 3 mammograms was reduced by 90 per cent using only FNA biopsy, clinical examination and information from the mammogram and without impairing considerably the reliability of the results.

Postoperative gastric ischaemia

M. Schein and R. Saadia

Department of Surgery, Medical School, University of the Witwatersrand, York Road, Parktown, 2193 Johannesburg, South Africa

Correspondence to: Mr M Schein

This review discusses postoperative gastric ischaemia after detailed consideration of the gastric blood supply and the effects of devascularization. Special consideration is given to gastric remnant necrosis, lesser curve ischaemia after highly selective vagotomy, and gastric ischaemia after other operations.

Keywords: Stomach, blood supply, postoperative ischaemia

Because of its abundant blood supply, the stomach has traditionally been held to be resistant to postoperative ischaemia. However, with the development of a large variety of operations which interfere drastically with the gastric blood supply, postoperative gastric ischaemia has been increasingly recognized. In this review, an outline of the gastric blood supply is given, the experimental basis for the occurrence of ischaemia is adduced, and the clinical syndromes of postoperative gastric ischaemia are examined.

Gastric blood supply

The arterial blood supply to the stomach, as outlined in the standard surgical texts, seems quite simple There are five sources of arterial supply which are held to be fairly constant. The coeliac trunk is the main contributor and gives rise to the following vessels: the left gastric artery, which is a direct branch of the coeliac trunk, the right gastric artery, which is usually a branch of the hepatic artery; the right and left gastroepiploic arteries, which originate from the gastroduodenal and splenic arteries respectively; and the short gastric arteries, which arise from the splenic artery.

In a study of 200 human cadavers, Michels[1] pointed out the limitations of the classical model by demonstrating the part played by at least six additional arteries. the superior pancreaticoduodenal, the superior duodenal artery of Wilkie, the retroduodenal, the transverse pancreatic, the dorsal pancreatic and the left inferior phrenic. Suzuki *et al.*[2] drew attention to the posterior gastric artery, described under various appellations by different authors. It was found arising from the superior aspect of the mid-third of the splenic artery in 62 per cent of cadavers. Its nutritional supply to the superior portion of the body and the fundus may be crucial to the viability of the stump after high gastrectomy and of the fundus after splenectomy. The contribution of the oesophageal arteries to the supply of the stomach is well documented in large anatomical studies[3,4] The extreme variability of the arterial supply to the stomach has been studied and an attempt has been made at codifying it in several types[5].

A better understanding of the intrinsic circulation may help to clarify the issue of gastric ischaemia. Two notable features are the absence of gastric end-arteries and the freely anastomotic nature of the intramural vessels[6] Complete filling of all the intramural vessels has been obtained in the cadaver by injection of any major artery after ligation of all the other extramural vessels; even the injection of a single short gastric artery seems to suffice. Such studies have supported the conclusion that 'The margin of safety in gastric operations involving mobilization of the stomach with ligation of major extramural vessels is probably as great or even greater than has been believed, and this fact should lend security in those instances in which such procedures are necessary '[7]. The clinical rarity of spontaneous gastric infarction is therefore not surprising. Cohen reported three cases of total gastric infarction but could not find any similar reports in the literature[8] However, thrombosis of the portal system or the coronary vein[9] are well documented causes of partial infarction of the stomach.

In the anterior and posterior walls of the body of the stomach, the rich mucosal plexus arises from a plexus of large submucosal vessels which in turn is supplied by branches from the extragastric arterial arcades. The lesser curvature is peculiar in this respect as its mucosal plexus is supplied directly from the extragastric arcades[6] As early as 1920, Reeves[10] emphasized the finer calibre and the smaller number of the anastomoses between adjacent branches in the lesser curvature region, resulting in their greater resistance to flow and predisposition to thrombosis. Piasecki[11] studied the vascular supply of normal stomachs and showed that some persons had patches of mucosa supplied by end-arteries. Because these patches occurred on the usual ulcer-bearing areas, he suggested that ischaemia plays a role in the initiation of peptic ulceration. Two studies provide extensive bibliographies on this theory[12,13].

Effects of experimental and surgical devascularization

The bulk of the experimental work on gastric devascularization was performed to assess its effects on gastric secretion, but the consequences of such procedures on gastric viability were also noted. In dogs, the effects of ligation of some or all of the vessels on the lesser curvature, greater curvature, or both curvatures were studied[14]: only complete devascularization of both curvatures resulted in gangrene of the stomach, and it was noted that the ischaemic injury affected only the greater curvature. This tolerance to partial gastric devascularization in the dog was confirmed but the ligation of all four major arteries was lethal[15]. Further work demonstrated that the preservation of the oesophageal arteries and a minor branch of the left gastric was sufficient to guarantee gastric viability, provided venous flow was not impeded[16]. A recent experimental study[17] demonstrated the resilience of the stomach to extensive devascularization by establishing a return to normal of the mucosal blood flow within a week.

In man, extensive surgical devascularization has been advocated from time to time. Somervell[18] performed 5000 'physiological gastrectomies' this operation involved the ligation of a large proportion of the gastric arteries on the assumption that hyperacidity would be relieved and recurrent ulceration prevented after gastroenterostomy; the problem of ischaemia is not even raised in his report. Ligation of the hepatic, splenic and left gastric arteries was also performed in a series of patients in an attempt to alleviate advanced portal cirrhosis[19], without resulting in ischaemia. An even more thorough devascularization, which left the stomach literally 'hanging on the right gastroepiploic artery' (and included a splenectomy), has also been recommended in portal hypertension[20]. Massive haemorrhagic gastritis was considered to be another indication for four-vessel ligation[21,22] and, even in instances where the spleen had already been removed, ischaemia did not complicate the procedure[23].

Postoperatic gastric ischaemia

Gastric remnant necrosis

In 1953, Rutter[24] was the first to report a case of ischaemic

0007-1323/89/080844-05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

necrosis of the gastric remnant following subtotal gastrectomy. The possibility of such a complication had been previously discounted: the surgeon was advised to divide the vessels 'until he deems a sufficient length has been denuded'[25] and it was suggested that 'the line of section is made so as to leave a small devascularized remnant'[26].

The precise incidence of postgastrectomy necrosis is difficult to determine. Only 20 cases could be traced in a review[27] in 1966. Gastric remnant necrosis occurred twice in one series of 604 cases of gastric operations[28] and four times in a personal series of 2000 gastrectomies[29]. Nevertheless, it is to be suspected that leakage at the gastroenteric anastomosis, a more common complication, may be due to relative ischaemia of the gastric remnant sufficient to impair healing but insufficient to produce overt gangrene. Such a hypothesis was put forward by several authors[27,28,30]; viewed from this perspective, the incidence of clinically significant gastric stump ischaemia would become more impressive.

Two experimental studies address the issue of the viability of the gastric stump after partial gastrectomy. Cate and Dawson[31] subjected dogs to a Billroth I gastrectomy of variable extent after ligation of all the major arteries to the stomach at their origin and splenectomy. The larger the remnant, the greater was the risk of necrosis: 20 per cent gastric remnants were associated with a 20 per cent incidence of necrosis, which increased to 80 per cent with 60 per cent residual gastric pouches. The ischaemic necrosis occurred uniformly on the greater curvature. Additional dissection around the oesophageal hiatus (and inevitable division of collaterals originating from the left inferior phrenic artery) increased the incidence of necrosis. Kilgore *et al.*[28] performed a 70 per cent gastrectomy and Billroth II anastomosis in dogs, with ligation of various combinations of arterial sources. Their study indicated that the risk of gastric remnant necrosis is high unless either or both the vasa brevia and the trunk of the left gastric artery are preserved

The clinical features of this complication and the means to prevent it are outlined in several reports[27–29,32–37] and in some textbooks[38,39]. It usually occurs between the 2nd and the 10th day. Its clinical presentation is that of general toxicity or septic shock in conjunction with peritonitis or a gastrocutaneous fistula. The latter, in isolation, represents a less severe degree of ischaemia. It is often difficult to foresee the occurrence of this complication. At operation, a pale or mottled appearance of the gastric remnant may well be a harbinger of ischaemic necrosis. However, it has been pointed out that the intraoperative recognition of the 'blue stomach syndrome' is not always followed by anastomotic leak or remnant ischaemia[40] and, on the other hand, a viable appearance is no guarantee against subsequent necrosis.

It is important for the surgeon to remember that the blood supply to the gastric remnant comes from three sources: the left gastric artery and its oesophageal branches, the splenic artery and its vasa brevia, and the left inferior phrenic artery. It seems essential to preserve one of these sources at the very least. For example, in a high gastrectomy with splenectomy for carcinoma, the left gastric is ligated at its origin together with the splenic artery: the frail phrenic branches constitute the only blood supply to the stump This situation is particularly precarious because in 2·6 per cent of patients, the left phrenic artery is a branch of the left gastric[41]: evidently, ligation of the latter at its origin may prove catastrophic Dissection at the gastro-oesophageal junction (in the performance of a truncal vagotomy, for example) may cause damage to the left inferior phrenic artery. Elderly and atherosclerotic patients may be particularly prone to ischaemic necrosis. Some authors have categorically stated that 'if the left gastric artery has been ligated proximal to its bifurcation and the spleen has been removed, the blood supply to the stomach has been so compromised that the surgeon is committed to total gastrectomy'[42].

The treatment of remnant necrosis calls for prompt reoperation and total gastrectomy. Although conservative treatment has occasionally proved successful, it is generally felt that a gastrocutaneous fistula caused by a significant area of necrosis is unlikely to respond to such a treatment[39]. In a collected series[37], the mortality rate of remnant necrosis was 70 per cent.

Lesser curvature ischaemia following highly selective vagotomy

Ischaemia of the lesser gastric curvature is a rare complication of highly selective vagotomy and most of the publications deal with isolated cases. In 1975, Johnston[43] reported only ten cases in a collected series of 5539 patients having highly selective vagotomy, an incidence of 0·2 per cent In 1983, Couinaud[44] studied this complication extensively in 45 patients, including two personal cases.

The pathogenesis of lesser curve ischaemia is probably multifactorial. The relative deficiency in the blood supply to this area of the stomach has already been mentioned. Multiple experimental studies[45–50] have demonstrated a reduction in the gastric mucosal blood flow after truncal or selective vagotomy, arguably caused by the opening of intramural arteriovenous communications. Several factors may contribute to the occurrence of this complication; they can be divided into three groups which relate to the patient's medical background, the type of operation performed (especially when other procedures are added to the vagotomy), and the technique of the highly selective vagotomy.

Old age has been incriminated as a risk factor[51] but, in Couinaud's review, 23 of the 29 patients whose age was known were under 60 years old[44]. Chronic conditions such as renal failure, hypertension, arteriosclerosis and diabetes mellitus have also been listed as risk factors and, for some[51], they constitute contraindications to the performance of highly selective vagotomy. This view is not shared unanimously Ischaemia has occurred in a few cases after highly selective vagotomy performed for a bleeding ulcer[44,52,53]; whether this constitutes an increased risk is not certain.

The incidence of this complication may well be increased when other procedures are added to the vagotomy. Because duodenal ulcer and gastro-oesophageal reflux often coexist, the combination of highly selective vagotomy and Nissen fundoplication has been advocated[54,55]. Furthermore, it has been claimed that the necessary sacrifice of some of the vasa brevia could be performed with impunity[55]. In a series of 33 such combined operations, three cases of lesser curve necrosis occurred, while there was only one such case in over 400 highly selective vagotomies performed by the same authors[56]. A similar observation was made by Kalsbeek who added a fundoplication to treat an accidental distal oesophageal tear[57]. The pathogenesis of this complication after the addition of fundoplication is unclear. Division of short gastric vessels was not performed in some of the cases[56]. A possible explanation may be massive gastric distention[56]; this is more likely to occur after fundoplication, a procedure well known to interfere with vomiting and belching. There is, in fact, some evidence that gastric distention decreases the arterial flow to the stomach[58,59], particularly in the lesser curve following highly selective vagotomy[60]. Indeed, the entity of spontaneous rupture–necrosis of the excessively distended stomach is well described[61–65] In the light of this hypothesis, it has been considered important to decompress the stomach routinely by means of a nasogastric tube or gastrostomy after combined highly selective vagotomy and fundoplication[56] The addition of splenectomy has also been incriminated in the occurrence of lesser curve necrosis[44,56]. The importance of splenic preservation in case of minor splenic injury during highly selective vagotomy has been stressed; the recommendation has also been made that the splenic vessels should be divided at the hilum, with preservation of the left gastroepiploic artery and some of the vasa brevia[44].

The operative performance of highly selective vagotomy has been scrutinized in search of an explanation for the occurrence of ischaemia. Caution has been expressed regarding the use of diathermy on the gastric wall[44]. Small bites of tissue must be taken when ligating the nerve fibres to the lesser curve, and 'digging into the muscle' of the lesser curve must be avoided[66]. The routine division of the right gastroepiploic vessels at the proximal border of the antrum is being practised by some authors[67–69] in an attempt to disrupt innervation via the terminal branch of the nerve of Latarjet. This manoeuvre may further impair the arterial supply to the lesser curve and may be inadvisable, especially if a Nissen fundoplication is planned or if splenectomy cannot be avoided[68,69].

Lesser curve ischaemia may manifest itself in one of three ways, depending largely on its degree and extent[44,52,70–80]: gastric perforation, gastrocutaneous fistula or gastric ulceration. Gastric perforation due to transmural necrosis may lead to a generalized peritonitis, usually relatively easy to recognize, or to a left-sided localized abscess which may be mistaken for a pleural or pulmonary complication[44]. It has been suggested that reperitonealization and invagination of the lesser curve may prevent free perforation, should transmural necrosis occur[75,79]. Others fear that this manoeuvre could further impair the precarious blood supply of the lesser curve[44].

The postoperative recovery after highly selective vagotomy is usually rapid: the diagnosis of perforation must be entertained in the face of any delay in the patient's postoperative progress. The diagnosis may be readily established by means of a Gastrografin® (Schering Health Care Ltd , Burgess Hill, UK) meal. Only prompt reoperation can decrease the otherwise high mortality rate. The choice of the correct surgical option depends on the size of the perforation and the condition of the peritoneal cavity. In favourable cases, excision and suture of the defect may suffice[73]. If a large area of lesser curve is involved, partial gastrectomy with excision of the ischaemic gastric tissue in its entirety is preferable[74]. In less serious cases of ischaemia, a gastrocutaneous fistula may develop[72]. In the absence of signs of intraperitoneal soiling, a trial of conservative treatment may prove successful but surgery is indicated if this fails.

Gastric ulceration developing after highly selective vagotomy probably represents the least severe form of ischaemia. These ulcers may be large and symptomatic, sometimes causing upper gastrointestinal haemorrhage, days[80], weeks[56], or even months[56,57] after the vagotomy On the other hand, gastric ulcers may be asymptomatic. they usually appear as small, shallow erosions at routine endoscopy[68,69,77]. The large, symptomatic ulcers respond poorly to medical treatment and the majority of them require gastrectomy[44]. Asymptomatic, superficial erosions can be managed conservatively with endoscopic surveillance until healing[68,69,77]. Routine endoscopy after highly selective vagotomy is practised by some authors[44,76] but its place remains uncertain

Gastric ischaemia following other operations

Gastric ischaemia is an infrequent complication of various upper abdominal procedures. In the literature, it is not emphasized to any great extent after operations such as the devascularization procedures used in portal hypertension. It is only sporadically reported after reoperations on the stomach for persistent or recurrent disease: for example, fundoplication may be hazardous even when undertaken years after a selective vagotomy and antrectomy[81] It is possible that its incidence has been somewhat underestimated because anastomotic leaks have not been explicitly acknowledged as a manifestation of ischaemia[39] There are, however, a number of operations where ischaemia is a more frequent cause of postoperative complications. These are discussed briefly.

Splenectomy. Harrison *et al.*[82] reported four personal cases of gastric fistula following splenectomy and collected 14 others from the literature. Ligation of the vasa brevia results in a significant decrease in blood supply to the apical segment of the greater curvature. Operative trauma and ischaemia, often in combination, were found to be the most important factors in the occurrence of this complication. If there is any anxiety about blood supply after splenectomy, the area of the greater curve most susceptible to ischaemia should be plicated with broad seromuscular sutures.

Gastric operations for morbid obesity. Gastric restrictive procedures using staplers have become the preferred operative treatment of morbid obesity Anastomotic leaks and gastric perforation are rare, but dreaded, complications[83]. Ischaemia may be an aetiological factor[84]. Cogbill and Moore reported two cases of perforation of the greater curvature of the proximal gastric pouch following a transverse gastroplasty[85]. Ischaemia was incriminated because the site of perforation was devascularized by division of the uppermost vasa brevia. The intraoperative use of intravenous fluorescein to detect ischaemic areas has been advocated. Vertical banded gastroplasty appears to be the safest gastric partitioning procedure, perhaps because it does not interfere with gastric blood supply[84]. A lethal case of perforation after a gastric banding procedure complicated by a splenectomy has been reported[86] and prompted an experimental study in cats, adding further evidence to support the ischaemic aetiology of this complication. If splenectomy becomes inevitable during the performance of a gastric partitioning operation, the procedure is best aborted[86].

Oesophageal surgery. The stomach is frequently used for oesophageal replacement or bypass in benign or malignant diseases. The mobilization of the stomach and its translocation into the thorax or the neck always necessitates the sacrifice of major arterial trunks. In most instances, blood supply is based on the right gastric and right gastroepiploic arteries with an intact intervening arcade. A different blood supply is sometimes preserved in less frequently used procedures. For example, the right gastroepiploic artery alone is preserved in the isoperistaltic gastric tube[87], the left gastric and left gastroepiploic arteries are preserved in the reversed oesophagoplasty[88], and the left gastroepiploic artery alone is preserved in the reversed gastric tube[89]. It is not surprising that ischaemic complications sometimes occur. Frank gastric necrosis has been reported[88] and perhaps it would have been recognized more frequently had all fatal cases come to post-mortem examination. Segmental gastric ischaemia has also been reported as a direct consequence of the use of stapling devices[90].

Conclusions

Despite a rich blood supply to the stomach, postoperative gastric ischaemia does sometimes occur. It is usually due to a combination of unfavourable anatomical circumstances as well as surgical factors. Ischaemia is produced when the capacity of the abundant gastric network of collaterals is exceeded. Frank gastric necrosis is a rare complication. Healing failure of a suture line may be more frequent and some cases may well be caused by unrecognized relative ischaemia. It behoves the surgeon to remember the normal gastric blood supply and its variations. He must also understand the patterns of restricted vascularization inherent to some operations or their combination Reoperation on the stomach by a different surgeon may be particularly hazardous. The high mortality rate associated with this rare but often lethal complication may be decreased by intraoperative attention to the adequacy of the gastric blood supply and appropriate management of doubtfully viable tissue. A high index of suspicion must be maintained postoperatively and should be followed, when indicated, by prompt reoperation.

Correspondence to: Mr E. R. Howard

Obstructive jaundice was the presenting feature in 12 patients with benign, non-traumatic strictures of the extrahepatic bile ducts. Ages at presentation ranged from 1·5 to 60 years and 11 were initially referred with diagnoses of malignant strictures. Histological examination, however, showed benign changes of chronic inflammation, with ulceration in seven, which were distinct from those of primary sclerosing cholangitis. All of the patients remain well from 3 to 14 years after surgery. The aetiology of the strictures is not known.

Keywords: Extrahepatic bile ducts, strictures, benign, non-traumatic

Benign, single, non-traumatic inflammatory strictures of the extrahepatic biliary system are very rare and have generally been considered to be a variant of extrahepatic primary sclerosing cholangitis. Primary sclerosing cholangitis is characterized by a chronic inflammatory fibrosis of the biliary tree, which usually affects both the intrahepatic and extrahepatic bile ducts[1]. Diffuse involvement of the extrahepatic ducts alone occurs in 20 per cent of patients[2,3] and rarely the disease has been described as localized to one segment[4–7].

Twelve cases of benign, non-traumatic inflammatory strictures of the extrahepatic biliary system treated between 1975 and 1986 are presented. The pathological and clinical features suggest that they should be regarded as a separate entity and not a variant of sclerosing cholangitis.

Patients and methods

Twelve patients who underwent resection of isolated strictures of the extrahepatic duct have been studied. Clinical and biochemical examination revealed obstructive jaundice in all 12. The age range was 1·5–60 years, and the female:male ratio was 7:5 (see *Table 1*). Investigations included ultrasonography and percutaneous transhepatic cholangiography; endoscopic retrograde cholangiography was also available in three patients. Radiology demonstrated a localized obstructing stricture in the extrahepatic biliary system with dilatation of the intrahepatic bile ducts in 11 of the 12 patients (*Figure 1*). A preliminary radiological diagnosis of malignancy was made in ten of the 12 patients.

None of the 12 patients had evidence of ulcerative colitis, mediastinal or retroperitoneal fibrosis, pancreatitis, orbital fibrosis, immunodeficiency syndromes or Peyronie's disease, all of which are associated with sclerosing cholangitis[4]. The strictures were not associated with gallstones and there was no history of previous surgery, except for one exploratory laparotomy.

All 12 patients underwent laparotomy; in 11, the macroscopic appearances of the extrahepatic biliary system suggested tumour, but in the other (case 9) no macroscopic abnormality was apparent. Seven lesions were excised before hepaticojejunostomy with a Roux-en-Y loop of jejunum. In one, a bypass hepaticojejunostomy was performed primarily. In case 9, with no external macroscopic abnormality, the common bile duct was opened and explored with the choledochoscope. A proliferative lesion was identified at the junction of the right and left hepatic ducts and this was excised with the biopsy forceps. A T tube was left in the common bile duct. In case 12, a small 'tumour' was palpable and was excised by choledochotomy and choledochoscopy.

Two cases were of particular interest and serve to illustrate the 'benign' nature of the clinical course of these lesions. A 15-year-old female patient (case 4) presented initially with painless obstructive jaundice. Percutaneous cholangiography demonstrated an obstructing lesion in the common hepatic duct, at the junction of the right and left hepatic ducts. Laparotomy was performed and an unresectable 'tumour' mass noted. No extrahepatic ducts were available for direct surgery and a biopsy only was performed. This was reported as embryonal rhabdomyosarcoma. She was transferred for further treatment. At repeat laparotomy T tube intubation was performed through the right hepatic duct with relief of the jaundice (*Figure 2*). Further biopsy showed hyperplastic biliary epithelium with underlying cellular granulation tissue including plasma cells and eosinophils. In places prominent spindle cells with eosinophilic cytoplasm were present; the cells were interpreted as myofibroblasts. She subsequently remained well and 2 years later was re-explored. Partial resolution of the mass had occurred and hepaticojejunostomy with a Roux-en-Y loop of jejunum was now possible. She remains well with normal liver function tests and radionuclide excretion scans 5 years after surgery.

A 25-year-old woman (case 6) presented with painless obstructive jaundice in 1975. Percutaneous transhepatic cholangiography demonstrated an obstructing lesion in the common hepatic duct, radiologically indistinguishable from a cholangiocarcinoma. At laparotomy, the mass was unresectable and tube intubation was performed (*Figure 3*). She subsequently remained well and had numerous tube changes. In 1986, tube change under radiological control was technically impossible and a second laparotomy was performed. This demonstrated that the mass had resolved and hepaticojejunostomy was performed with a Roux-en-Y loop of jejunum.

Table 1 *Summary of cases of benign, non-traumatic inflammatory strictures of the extrahepatic biliary system*

Case no.	Sex	Age at presentation (years)	Operation	Follow-up (years)
1	M	1·5	Excision, Roux-en-Y reconstruction	5
2	F	6	Excision, Roux-en-Y reconstruction	10
3	F	13	Excision, Roux-en-Y reconstruction	12
4	F	15	Intubation, subsequent hepaticojejunostomy	7
5	M	24	Hepaticojejunostomy	8
6	F	25	Intubation, subsequent hepaticojejunostomy	14
7	F	34	Excision, Roux-en-Y reconstruction	3
8	M	39	Excision, Roux-en-Y reconstruction	5
9	F	44	Intubation, choledochoscopic biopsy excision	3
10	M	51	Excision, Roux-en-Y reconstruction	12
11	F	55	Excision, Roux-en-Y reconstruction	12
12	M	60	Intubation, choledochoscopic biopsy excision	12

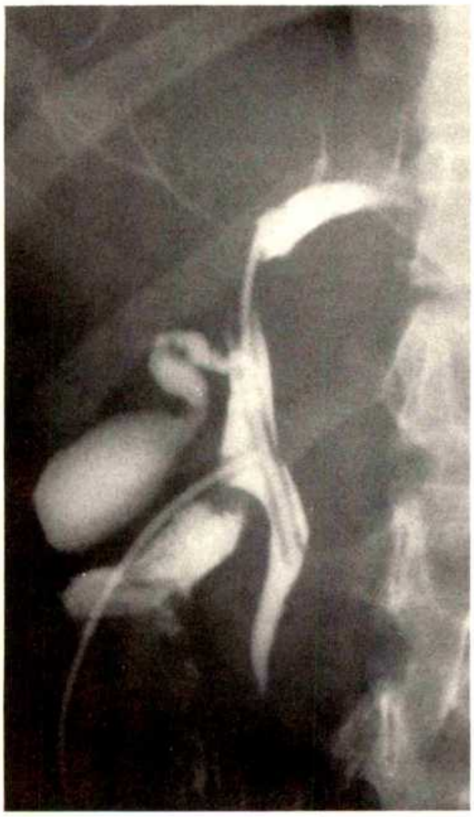

Figure 2 *Stricture of the common hepatic duct in a 15-year-old female patient treated initially with a* T *tube, and later with hepaticojejunostomy (case 4)*

Results

A total of 16 extrahepatic bile duct biopsies were reviewed from the 12 patients (ten common bile duct, five common hepatic duct, one cystic duct).

Four main histological features were seen in the biopsies (*Figures 4* and *5*).

1. *Chronic inflammation*: evidence of chronic inflammation was present in all biopsies but varied from a mild, patchy, predominantly perivascular infiltrate of lymphocytes and plasma cells in some cases to solid sheets of lymphoid cells in others. A few biopsies contained eosinophils and/or histiocytes but these were always a minor component compared with the lymphocytes and plasma cells. Very few biopsies contained polymorphs.
2. *Ulceration*: seven of the biopsies showed extensive ulceration of the surface epithelium while a further six showed small areas of ulceration.

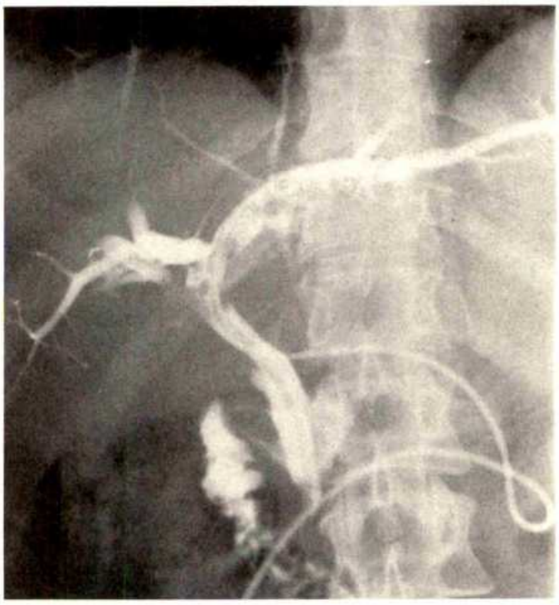

Figure 3 *Stricture of the common hepatic duct in a 25-year-old woman with a* T *tube in place (case 6)*

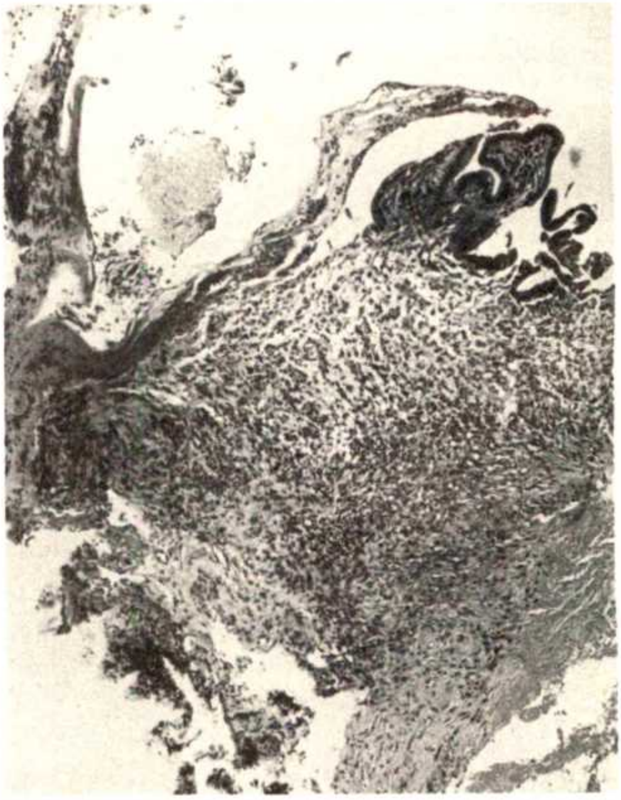

Figure 4 *Bile duct biopsy showing ulceration, hyperplastic epithelium and densely inflamed granulation tissue (original magnification × 90)*

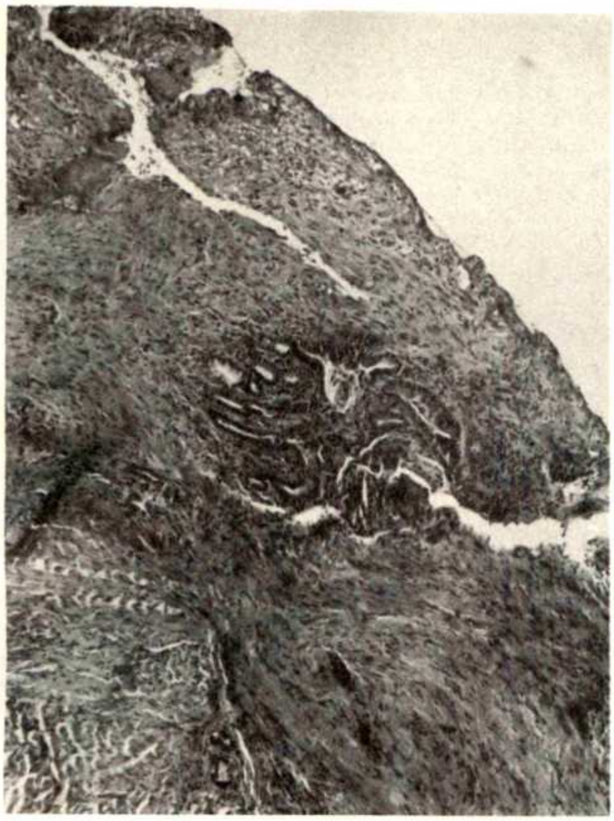

Figure 5 *Bile duct biopsy showing an island of hyperplastic epithelium surrounded by dense fibrous tissue (original magnification × 90)*

3. *Fibrosis and/or granulation tissue*: granulation tissue was commonly present immediately below the bile duct epithelium. Fibrosis was present in almost all biopsies and in all layers of the bile duct wall, sometimes accompanied by a myxoid ground substance. The fibrosis had obliterated much of the smooth muscle normally present in the walls of the extrahepatic bile ducts. Occasional spindle cells with eosinophilic cytoplasm and large, irregular and hyperchromatic nuclei were present in the stroma. These probably represent active fibroblasts or myofibroblasts.
4. *Changes in bile duct epithelium*: the epithelial changes took several forms. Epithelium adjacent to areas of ulceration showed some hyperplastic and regenerative features with enlarged, occasionally hyperchromatic, nuclei. Irregular glandular structures were present in some biopsies, either at the luminal surface or trapped within areas of fibrosis (*Figure 5*). In a few biopsies, the appearance of the glands, composed of cells with large, hyperchromatic and irregular nuclei, had been interpreted as suggestive of carcinoma.

Of these four main features (chronic inflammation, ulceration, fibrosis, and epithelial changes) at least three were present in each case. The mucosal ulceration in particular suggests that these strictures are caused by a process distinct from sclerosing cholangitis as the epithelium remains intact in that disease. The tissue response of fibroblastic proliferation rather than polymorphonuclear infiltration in the extrahepatic bile ducts is in keeping with a chemical rather than a bacterial cause for the inflammation. In some biopsies, the epithelial changes were suggestive of malignancy but the clinical course and, when taken, subsequent biopsies show these to be hyperplastic or regenerative.

Discussion

Benign, inflammatory, non-traumatic strictures of the extrahepatic bile ducts are extremely rare[7]. Primary sclerosing cholangitis is a rare disease characterized by chronic inflammatory fibrosis of the biliary tree with intact mucosa[8], usually affecting both the intrahepatic and extrahepatic ducts[1-8]. The diagnosis of primary sclerosing cholangitis rests on the cholangiographic demonstration of stricturing and beading of the biliary tree in the absence of other causes of ductal stenosis[2]. Primary sclerosing cholangitis is a disease of unknown aetiology, which must be distinguished in particular from cholangiocarcinoma, from which it may be very difficult to differentiate[9]. In patients who have primary sclerosing cholangitis affecting the extrahepatic biliary tree, cholangiography shows characteristically alternating areas of constriction and dilatation involving the entire bile duct[1-3]. However, it has been shown[7,10] that sclerosing cholangitis may affect only a segment of the extrahepatic ducts, mimicking a cholangiocarcinoma. Nevertheless, this possibility has been considered to be very infrequent, and according to Longmire *et al.*[11] most authors consider that any localized obstruction in the extrahepatic bile duct coexisting with dilatation of the intrahepatic radicles should be interpreted as cholangiocarcinoma until proved otherwise.

The radiological appearances are often interpreted as cholangiocarcinoma, possibly with extensive ductal involvement. Although the radiological appearance in the case reported by Panes *et al.*[12] suggested that sclerosis involved only a small segment of the common hepatic duct, the histological examination, as well as the surgical findings, indicated more extensive involvement of the extrahepatic biliary tree and this has also been recently observed by others[2,6]. Hadjis *et al.*[7] reported eight patients with isolated extrahepatic strictures and also suggested that they represented localized forms of sclerosing cholangitis.

The 12 cases presented here are all histologically proved examples of benign, inflammatory, non-traumatic stricturing of the extrahepatic bile ducts. All underwent preoperative cholangiography, laparotomy and biopsy and all have subsequently had long-term follow-up with no deaths. Several factors are of interest in this series. First, ten of the 12 were confidently diagnosed as malignant on radiological assessment. Secondly, the histological examination has shown mucosal ulceration, suggesting that the process of inflammation in these cases is not the same as in sclerosing cholangitis, where there is a non-specific diffuse fibrotic thickening of the bile duct wall with the mucosa remaining intact. The prognosis appears to be good after surgical bypass, whereas the treatment of sclerosing cholangitis is unsatisfactory and the prognosis poor, with recurrent acute cholangitis, cirrhosis and bleeding from varices[4]. In one series the mean duration in 11 patients from the onset of symptoms to death was 7 years[1], which compares with a mean follow-up period of 8·6 years in our patients. Six of our patients are now more than 10 years from diagnosis with no evidence of either sclerosing cholangitis or malignancy in the biliary tract. Thirdly, in several cases that were initially inoperable, tube intubation allowed relief of the jaundice and the inflammatory process subsequently resolved spontaneously (even after several years), allowing bypass with a Roux-en-Y loop of jejunum. Fourthly, it is of some concern that in previous publications that recommended stenting of biliary strictures[13] or irradiation of cholangiocarcinomas with iridium-192 wire[14] tissue for histological examination was not obtained in all cases. It is possible that some cases may have received inappropriate treatment.

In conclusion, we agree with previous authors[7] that biopsy tissue should be obtained whenever possible in cases of extrahepatic biliary strictures that present with dilatation of the intrahepatic ducts as radiology alone is often insufficient to make a firm diagnosis of malignancy. Intubation should not be considered permanent in cases with benign histology, and follow-up radiology with second laparotomy may be valuable as spontaneous regression of the inflammatory process can occur. The histological observations in this series suggest that benign strictures of the extrahepatic ducts may occur without evidence of sclerosing cholangitis, and the prognosis after surgical resection appears to be very satisfactory.

Acknowledgements

We are grateful to Mr J. L. Dawson and Mr H. E. Berry for allowing us to report two cases under their care, and to Dr R. Williams and Dr A. P. Mowat for referring three cases.

Street, Dublin 7, Ireland

A morphological study of the pancreatic microvasculature in experimental pancreatitis was performed in dogs, using three-dimensional scanning electron microscopy vascular casting and transmission electron microscopy. Animals with pancreatitis were characterized by a marked reduction in the number of capillaries outlined by the cast and by distortion of those that were outlined, with irregularity of the capillary lumen, abruptly terminating capillary buds and leakage of the cast material through the capillary membrane. The study provides convincing morphological evidence that one of the earliest changes in acute pancreatitis is distortion of the capillary circulation.

Keywords: Pancreas, blood supply, experimental pancreatitis, caerulein, electron microscopy

Perfusion studies of the isolated pancreatitis model suggest that one of the earliest changes in acute pancreatitis is an alteration in capillary permeability[1]. The aim of the present investigation was to perform a three-dimensional morphological study of the pancreatic microvasculature in an *in vivo* experimental model using a combination of scanning electron microscopy (SEM) and transmission electron microscopy (TEM).

Materials and methods

Ten adult mongrel dogs were anaesthetized using 5 per cent chloralose in 25 per cent urethane ($1{\cdot}5\,\mathrm{ml\,kg^{-1}}$). Group A animals (five dogs) received a 2-h intravenous infusion of normal saline ($30\,\mathrm{ml\,h^{-1}}$) while group B animals (five dogs) received a 2-h infusion of caerulein ($10\,\mu\mathrm{g\,kg^{-1}\,h^{-1}}$ at $30\,\mathrm{ml\,h^{-1}}$). The caerulein was dissolved in 1:10 saline dilution of the dogs' own serum. Blood was removed for serum amylase determination before infusion, at 20-min intervals during infusion, and again at the end of the 2-h infusion period.

Laparotomy was then performed and all the minor vessels leading to the right lateral lobe of the pancreas were isolated and ligated. The inferior pancreaticoduodenal artery was cannulated using a 21 Fr cannula and the inferior pancreaticoduodenal vein was ligated. A ligature was then tied tightly around the medial portion of the right lobe, effectively isolating it from the body of the pancreas, and a single venous outlet was created by incising the main vein which courses along the dorsal surface of the gland at the medial aspect of the right lateral lobe. The right lobe was then perfused via the cannula, firstly with normal saline (20 ml) and then with 2·5 per cent glutaraldehyde (20 ml). Twenty minutes later the lobe was perfused with a low viscosity casting medium, Mercox® (20 ml) (Ladd Research Industries Incorporated, Burlington, Vermont, USA). The casting material was allowed to dry and harden for 20 min.

The casted pancreas was digested for 7–10 days in 34 per cent potassium hydroxide at 40°C. When digestion was complete, the cast was washed to neutrality, dried in air, coated with gold and examined using SEM.

Specimens of the fixed pancreas perfused with saline and glutaraldehyde alone were prepared for TEM using standard methods[2]. Sections were stained with uranyl acetate and lead citrate and examined in a JEOL 2000 EX® (Japanese Electron Optics Ltd., Tokyo, Japan) electron microscope. Semi-thin sections were stained with toluidine blue for light microscopy.

Results

Pancreatitis was induced in all five group B animals, as evidenced by a significant rise in serum amylase levels (*Figure 1*), histological examination (*Figure 2*) and gross appearances at laparotomy (the gland was inflamed and oedematous with clear delineation of individual lobules by the oedema).

SEM studies of casts of the normal and inflamed pancreas are compared in *Figures 3–5*. Pancreatitis specimens were characterized by a gross reduction in the number of capillaries outlined by the cast (*Figure 3*). Those that were outlined were irregular, and several ended abruptly in smoothly tapered ends (*Figure 4*). Blebs of cast were visible along the capillary surface, suggesting leakage of casting material through the capillary wall (*Figure 5*).

The findings on SEM were supported by cross-sectional TEM views of the capillary lumen: the group of animals with pancreatitis was characterized by irregularity of the endothelial capillary lining (*Figure 6*).

Discussion

Caerulein is an analogue of cholecystokinin, a known stimulant of pancreatic exocrine secretion, and when it is administered

in supramaximal doses, as it was in this study, it induces an interstitial oedematous pancreatitis[3]. The caerulein model has been widely used in the rat[3–6] but reports in the literature of the use of the canine model are rare[7,8]. In the present study, histological examination confirmed that the pancreatitis was oedematous in nature, similar to that reported in the rat[5]. Acute necrotizing pancreatitis has been described in dogs using a caerulein infusion model[7], but in that case histological examination was carried out 12 h rather than 2 h after commencement of the infusion.

The pancreatic microcirculation in pancreatitis has been previously investigated using angiography and light microscopic examination of vascular casts. Some of the features reported above have been described[9–11], but the combination of SEM and TEM provides a more detailed and more accurate three-dimensional study[12]. Abruptly terminating small arteries have been reported using light microscopy[10] but analysis using SEM and TEM in this study confirms that these abruptly terminating vessels are capillaries, which may explain the gross reduction in the extent of capillaries outlined by the cast in pancreatitis. Why the vascular casts should terminate so abruptly is unclear. There was no evidence of intravascular thrombosis found on cross-sectional examination by TEM.

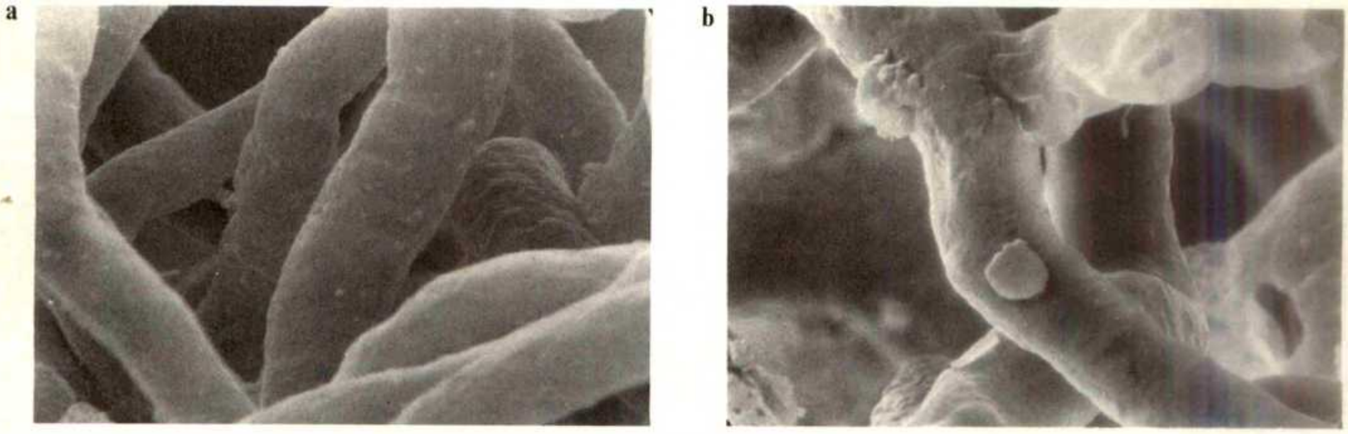

Figure 5 *Scanning electron photomicrographs of the dog pancreas after* **a** *saline and* **b** *caerulein infusion, showing blebs of cast on the capillary surface in animals with pancreatitis, suggesting leakage through the capillary wall. (Original magnification* × *3000)*

Precapillary sphincters have been identified in the cat pancreas[11] and the possibility of such sphincters in the dog is supported by evidence of local arteriovenous shunting in other canine pancreatitis models[10,13]. Such sphincters could explain the paradoxical findings in the caerulein model of an increase in pancreatic blood flow[9] despite a reduction in the number of perfused capillaries; perhaps the abruptly terminating capillary casts are the result of impaired flow due to sphincter spasm.

The irregular outline of the capillary casts in this and other studies[10,11] has been attributed to external compression of the capillaries by oedema but the findings on TEM in this study strongly suggest that the irregularity is due to disruption of the capillary endothelial lining, which could in turn explain the altered capillary permeability reported to occur early in the disease process[1].

The combination of longitudinal SEM views of casts of the vascular tree and cross-sectional TEM views of the vascular lumen provides an ideal technique for a detailed three-dimensional study of the visceral microcirculation. The technique demonstrated early distortion of the local microcirculation in the development of pancreatitis; further studies are underway to assess the time factor involved in these changes and to evaluate the microcirculation in the pancreas and other organs known to be impaired in this and other established models of pancreatitis.

Endoscopic sphincterotomy was performed in 121 patients (age range 34–92 years; median 80 years) with intact gallbladders and bile duct stones. Clearance of the duct by basket or balloon extraction was attempted in 97 patients (80 per cent) and achieved in 93 of these patients (96 per cent). In 24 patients the duct was left to empty spontaneously and this occurred in 22 patients. Immediate complications due to endoscopic sphincterotomy occurred in five patients (two haemorrhage, two perforation, one haemorrhage and perforation). Of the 101 patients reviewed 12–72 months (median 24 months) after endoscopic sphincterotomy, 76 (75 per cent) have remained asymptomatic throughout the follow-up period. Eighteen patients (18 per cent) required cholecystectomy for recurrent gallbladder symptoms 1–24 months after endoscopic sphincterotomy. One of the asymptomatic patients underwent cholecystectomy on the advice of his consultant. A further seven had recurrent biliary colic or cholangitis necessitating enlargement of the sphincterotomy and further stone retrieval in three of these patients. Endoscopic sphincterotomy is an effective treatment for bile duct stones in high risk patients, but subsequent cholecystectomy is required in a significant number of patients owing to continuing gallbladder symptoms.

Keywords: Common bile duct, endoscopic sphincterotomy

The use of endoscopic sphincterotomy to remove bile duct stones is increasing rapidly, especially in elderly, infirm patients. While this technique avoids surgery in the short term, remaining cholelithiasis can cause biliary colic, acute or chronic cholecystitis, and even jaundice. If these symptoms are severe or persistent, cholecystectomy may be necessary. It has been suggested recently, however, that surgery will be required only rarely provided the bile duct is cleared at the time of endoscopic sphincterotomy[1]. The aim of this study was to assess the natural history of patients with cholelithiasis following endoscopic sphincterotomy for choledocholithiasis, with particular reference to the need for subsequent cholecystectomy.

Patients and methods

Endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy were performed in 121 patients with intact gallbladders and bile duct stones. Seven of these patients required a second ERCP to achieve adequate sphincterotomy. Many of the patients were referred specifically for ERCP from other hospitals in the west of Scotland. All patients were seen by one or more of the surgical authors soon after admission, and in view of age and general fitness it was decided to adopt non-surgical management in the first instance. The 52 men and 69 women patients had a median age of 80 years, ranging from 34 to 92 years. The 34-year-old was a grossly obese woman who presented with deep jaundice and markedly disordered liver function tests. Eighty-three per cent of patients were aged 70 years or more and 55 per cent were aged 80 or more. The main presenting features were jaundice in 70 patients, cholangitis in 22, pain in 19 and acute pancreatitis in seven. Three elderly patients presented with vague confusion states and were found to have upset liver function tests. Many patients had a combination of signs and symptoms. No patient exhibited clinical features suggestive of significant gallbladder inflammation at the time of sphincterotomy. Significant cardiovascular disease was present in 48 patients and obesity in 14 patients. Other coexisting illnesses included cerebrovascular disease, diabetes mellitis, multiple sclerosis, connective tissue disorders and abdominal aortic aneurysm.

ERCP and endoscopic sphincterotomy were performed under intravenous sedation and antibiotic cover when appropriate. The Olympus JF1T 10 duodenoscope (KeyMed, Southend-on-sea, UK) and a sphincterotome attached to adiathermy unit were used. An active policy of bile duct clearance following sphincterotomy was not adopted routinely, but attempts were made to remove stones greater than 1 cm in diameter using a Dormia basket or a balloon catheter. In the event of failure to clear the duct in such circumstances, repeat ERCP was performed during the same admission, usually within 1 week. In a small number of patients with large bile duct stones (1–2 cm), nasobiliary catheter drainage was established before either stone extraction or methyl tertiary butyl ether (MTBE) stone dissolution. If the duct contained only small stones, these were left to pass spontaneously, in which case a repeat ERCP was performed 4–6 weeks later, or immediately in the event of further symptoms. Patients were reviewed at a surgical outpatient clinic.

Results

The outcome of the 121 patients who underwent endoscopic sphincterotomy is summarized in *Figure 1*.

Stone retrieval (Table 1)

Of the 93 patients whose ducts were cleared during the first admission, this was achieved at the first attempt in 57 patients. A further ERCP during the same admission in the remaining 36 patients revealed spontaneous duct clearance in 12, while in 18 patients the duct was cleared subsequently using a Dormia basket. Six patients with large stones required nasobiliary catheter insertion followed by MTBE stone dissolution therapy and/or stone extraction. Three patients had large stones which could not be caught by the basket, and they required surgical clearance of the duct. One further patient required surgery to remove the Dormia basket which became impacted in the bile duct after snaring a large stone. Twenty-two of 24 patients in whom duct clearance at the time of endoscopic sphincterotomy was not attempted had clear ducts at review ERCP 4–6 weeks later. Overall, of the 117 patients whose ducts were cleared endoscopically, 91 required one ERCP examination, 23 required two, and three required three ERCPs to empty the duct.

Bile duct confirmed as empty at check ERCP	(22)
Stones remaining but cleared at check ERCP	(2)

ERCP, endoscopic retrograde cholangiopancreatography; ES, endoscopic sphincterotomy

Complications (Table 2)

Three patients suffered retroperitoneal perforation at endoscopic sphincterotomy, were treated conservatively, and survived. Of the three patients with haemorrhage following endoscopic sphincterotomy, one required emergency surgery and subsequently died. At follow-up the bile duct was clear in the four surviving patients who had sustained perforation and/or haemorrhage. Three of the six patients with cholangitis had this before endoscopic sphincterotomy, while four of the nine patients with acute symptomatic pancreatitis had pancreatitis before endoscopic sphincterotomy. Asymptomatic hyperamylasaemia (range 312–5290 units/l) occurred in 30 (25 per cent) patients.

Of the six patients with cholangitis four subsequently died. One of these patients, who required a wide endoscopic sphincterotomy for a large stone and pus in the bile duct showed evidence of continuing biliary sepsis and required laparotomy 6 days later. The principle cause of sepsis was found to be empyema, and the bile duct was noted to be empty of stones. Cholecystostomy was performed but the patient died of a myocardial infarction 24 h later. One patient whose bile duct was partially cleared at initial endoscopic sphincterotomy underwent repeat ERCP for features of continuing cholangitis, but was confirmed at this examination to have an empty bile duct. This patient died 1 month later from bronchopneumonia. Two patients had a wide endoscopic sphincterotomy performed in the presence of tiny bile duct stones, where nasobiliary drainage was not thought to be necessary. Despite apparent free bile drainage one patient died 5 days and the other 8 days after endoscopic sphincterotomy from presumed continuing cholangitis. Five of the nine patients with acute pancreatitis had the bile duct cleared at the first attempt. The pancreatic duct was outlined in eight of these patients.

There were seven in-hospital deaths occurring up to 36 days after endoscopic sphincterotomy. In addition to the patient who required surgery for haemorrhage and the four patients discussed above, the patient who required surgery for removal of the impacted Dormia basket died of respiratory failure. A further patient died of pancreatitis, which had been the presenting complaint before endoscopic sphincterotomy.

Follow-up

Of the 121 patients who entered the study, ten patients died of unrelated diseases. Four patients required early surgery for large bile duct stones during their initial admission. One of these patients and six others died during their initial hospital stay. Thus, 101 patients were available for review in a median follow-up of 24 months (range 12–70 months).

Seventy-six patients had remained asymptomatic throughout the follow-up period, while 25 had experienced further biliary tract symptoms. Eighteen of these 25 patients, plus one asymptomatic patient, underwent cholecystectomy 1–24 months after sphincterotomy.The reasons for surgery are shown in *Table 3.* Of the seven patients who came to surgery because of recurring episodes of cholecystitis, five required urgent laparotomy for empyema of the gallbladder. Initial surgery in one of these patients was limited to cholecystectomy. In 11 of the 25 patients, the bile duct had not been cleared, yet at the time of cholecystectomy operative cholangiography revealed

Table 2 *Complications of endoscopic retrograde cholangiopancreatograpy and endoscopic sphincterotomy*

Complication	Number of patients
Retroperitoneal perforation	3 (2·5)*
Haemorrhage from ES site	3 (2·5)*
Cholangitis	6 (4·9)
Acute symptomatic pancreatitis	9 (7·4)

* These six complications occurred in five patients, with one patient having both perforation and haemorrhage, ES, endoscopic sphincterotomy

Table 3 *Reasons for cholecystectomy*

	Number of patients	Number of patients with stones in gallbladder	Number of patients with stones in bile duct
Biliary colic	10	9	2
Cholecystitis/empyema	7	7	—
Recurring biliary colic and jaundice	1	1	1
Consultant decision*	1	1	1

* Asymptomatic patient; none of the four patients with bile duct stones underwent surgery because of symptoms primarily relating to the presence of duct stones

bile duct stones in only four patients. One of the patients operated on for recurring biliary colic had no stones in the gallbladder by the time of cholecystectomy but had one stone in the bile duct, while another patient had stones both in the gallbladder and bile duct. In both these cases, the duct had been cleared of stones at the time of endoscopic sphincterotomy. One patient underwent surgery on the advice of the consultant in charge because of cholelithiasis but had been asymptomatic. Despite complete duct clearance, this patient was shown at cholecystectomy to have a further bile duct stone.

Seven patients have had recurring biliary symptoms but, as yet, have not required cholecystectomy. Four of these patients have had recurring episodes of biliary colic. This settled spontaneously in two patients but the other two required enlargement of the sphincterotomy to remove further bile duct stones. These four patients had clear ducts following initial endoscopic sphincterotomy. Three patients have had recurring attacks of cholangitis, necessitating repeat ERCP and duct clearance. Two of these patients died shortly after this review, one of peptic ulcer haemorrhage and the other of persisting cholangitis. This latter patient had been admitted to another unit where it had been decided that further intervention was inappropriate. Post-mortem examination confirmed the presence of a further stone within the bile duct

Discussion

Endoscopic sphincterotomy is an effective treatment for symptomatic bile duct stones in high risk patients, although the procedure is not free of complications. The immediate complications and mortality rate in the present series compare favourably with other reported studies[2–4]. In a recent study of 114 patients with intact gallbladders, Neoptolemos *et al.*[5] reported 22 major complications and nine deaths following endoscopic sphincterotomy. These authors suggested that the mortality rate may be reduced by improved management of complications. Haemorrhage following sphincterotomy can be rapid and fatal, or may be manifested only by a fall in haemoglobin concentration. When haemorrhage is severe enough to warrant operative intervention, survival is rare[1,6]. Complication and mortality rates must be viewed in the light of the patient population involved. Usually, sphincterotomy is performed because the patient is deemed an unacceptable surgical risk; therefore, if surgery becomes necessary due to a complication or failure of the technique, the outcome is inevitably poor. Thus, if sphincterotomy fails to clear the bile duct of large stones, alternative management such as the insertion of nasobiliary catheters followed by stone dissolution[7] or the use of endoprostheses[8] should be considered. Further possibilities such as extracorporeal shock wave lithotripsy remain to be evaluated.

This study demonstrates that although endoscopic sphincterotomy is an effective treatment, subsequent cholecystectomy is required in 18 per cent of patients due to continuing gallbladder symptoms. This conclusion differs from the findings of Martin and Tweedle[1], who suggested that cholecystectomy was not required provided the bile duct was cleared. In the present study, no routine attempt was made to clear the bile duct of small stones unless cholangitis was present. In the majority, the duct was clear when ERCP was repeated 4–6 weeks later. Furthermore, there was no correlation between duct non-clearance and the need for subsequent cholecystectomy.

It would be of value to be able to predict those patients who will require subsequent cholecystectomy. It has been suggested that if the gallbladder does not fill at ERCP, indicating probable cystic duct obstruction, then cholecystectomy is likely to be required[9,10], but this suggestion has not been supported by other series[1,11]. Indeed, in the present study filling of the gallbladder occurred in seven of the 18 patients who required subsequent cholecystectomy Furthermore, among the 83 patients who have not required cholecystectomy, no gallbladder filling occurred in 61. Indeed, of the 22 patients in whom gallbladder filling was seen, two have had recurring biliary symptoms. The presence of pre-existing cholangitis has been said to indicate likely gallbladder complications at a later date[11], but in the present series only six of the 18 patients who subsequently required cholecystectomy presented with cholangitis. Several patients in this series with gallbladders *in situ* illustrate that ducts initially cleared by endoscopic sphincterotomy may later show evidence of stones after further gallbladder colic.

In conclusion, while endoscopic sphincterotomy is an effective tretment for choledocholithiasis in this group of high risk patients, subsequent cholecystectomy was required in 18 per cent of patients due to recurring gallbladder symptoms. As the minimum follow-up of this group is currently 1 year, and because some of the patients who required cholecystectomy did so in the second year of follow-up, it is possible that more of these patients may require surgery as the study progresses

The relationship between pancreatic duct pressure, duct permeability to macromolecules and the development of acute pancreatitis was studied in a cat model. Perfusion of the pancreatic duct with 15 mM glycodeoxycholic acid, ethanol administration, or secretagogue-stimulated pancreatic secretion against >50 per cent duct obstruction resulted in an increase in peak pancreatic duct pressure in all animals. Duct permeability to 20 000 molecular weight dextran molecules was increased in 22 of 29 experimental animals compared with two of 22 control animals ($P<0{\cdot}01$)*. Perfusion of the pancreatic duct with activated pancreatic enzymes resulted in acute pancreatitis in 24 of 29 experimental animals compared with three of 22 control animals* ($P<0{\cdot}01$)*. These results suggest that pancreatic ductal hypertension, resulting in increased ductal permeability to large molecules, may be a common early event in gallstone and alcoholic pancreatitis.*

Keywords: Alcohol, pancreatic duct, pressure, duct permeability, acute pancreatitis

Under normal circumstances pancreatic proenzymes are secreted into the pancreatic duct and are activated in the duodenum by the enzyme enterokinase. Premature activation of these proenzymes within the pancreas is thought to be an important early event in the pathogenesis of acute pancreatitis. The mechanism by which activated pancreatic enzymes gain access to the pancreatic parenchyma is unknown. Previous work from our laboratory suggests that under certain circumstances the cat pancreatic duct becomes permeable to molecules the size of pancreatic enzymes[1,2]. In those experiments, ductal perfusion with a bile salt or the oral administration of alcohol led to an increase in duct permeability to large molecular weight dextran molecules. When the duct was subsequently perfused with activated pancreatic enzymes, acute pancreatitis resulted. Perfusion of a non-permeable duct with active enzymes or perfusion of a permeable duct with inactive enzymes resulted in little or no histological damage to the pancreas. Pancreatic duct obstruction has also been implicated in the pathogenesis of acute pancreatitis. In these experiments we examined the relationship between pancreatic duct pressure, duct permeability and the development of acute pancreatitis in three models of the disease.

Materials and methods

Mongrel cats were anaesthetized with intramuscular xylazine (1 mg/kg) and intraperitoneal sodium pentobarbitone (25 mg/kg). A femoral vein was cannulated for the administration of fluid and drugs. Through a midline laparotomy incision the pancreas was exposed throughout its length. Three different experimental systems were used.

Experiment 1

In this experiment the effect of bile salt perfusion of the pancreatic duct on pancreatic duct pressure, duct permeability and the development of pancreatitis were studied. The pancreatic duct was cannulated in the head and tail of the gland using fine polyethylene tubing (*Figure 1*). Pancreatic duct pressure was measured via a pressure transducer connected to the cannula in the tail of the gland. The duct was perfused with a standard perfusate containing (HCO_3^-) 120, (Cl^-) 30, (Na^+) 150 mmol/l, pH 8·4 and osmolality 315 mosmol/l at 0·5 ml/h for 30 min to stabilize the system. Then the duct was perfused with either standard perfusate or 15 mM sodium glycodeoxycholate at the same rate of perfusion for 1 h. Pancreatic duct pressure was measured continuously throughout the perfusion period. Ductal permeability was assessed by measuring the recovery of 20 000 molecular weight fluoresceinated dextrans in portal venous blood following their perfusion along the pancreatic duct. The design of the system was such that if dextrans were recovered in portal venous blood they could only have got there by traversing the ductal system.

In a separate group of cats the pancreatic duct was cannulated in the tail of the gland. The duct was perfused with standard perfusate or sodium glycodeoxycholate as before and then perfused with pancreatic enzymes for 1 h at 0·5 ml/h. These enzymes were obtained from separate donor cats by collecting secretin/cholecystokinin-stimulated pancreatic juice and standardized to an amylase concentration of 35 units/ml. The enzymes in this juice were activated by *in vitro* incubation with porcine enterokinase. The cannulae were removed and the cannulation sites ligated. The abdomen was closed and the animals allowed to recover. The pancreas was examined for the presence of oedema and haemorrhage 24 h later and samples of the pancreas were excised for histological examination. Coded slides from each animal were examined by two independent observers for the presence of oedema, inflammatory cell infiltration and parenchymal necrosis. An 'inflammatory score' of 0–4 (with 4 representing the most severe changes) was given for each parameter and a total score of 0–12 derived by addition.

Experiment 2

In this experiment the effect of ethanol was studied. The pancreatic duct was cannulated in the tail of the gland as before and the duct perfused with standard perfusate for 30 min. The stomach was cannulated and the cats received either 20 ml of normal saline or 20 ml 40 per cent ethanol intragastrically over a 10-min period (*Figure 2*). Pancreatic duct pressure was measured continuously for 1 h during which the duct was perfused with standard perfusate at 0·5 ml/h. Serum ethanol levels were measured 1 h after ethanol instillation. Duct permeability was measured as before. In a separate group of cats the pancreatic duct was perfused with activated pancreatic enzymes 1 h after saline or ethanol administration and samples of the pancreas examined 24 h later.

Experiment 3

In this experiment the effect of pancreatic duct obstruction was studied. The pancreatic duct was cannulated in the tail of the gland as before. The duct in the head of the gland was isolated and 0, 25, 50, 75 or 100 per cent of its luminal diameter was obstructed with a microvascular clip, using a dissecting microscope to aid the placement (*Figure 3*). The gland was stimulated to secrete by an intravenous bolus injection of secretin (2·0 units/kg) and cholecystokinin octapeptide (0·08 μg/kg) and the pancreatic duct pressure was measured continuously for 1 h. Then the obstructing clip was removed, duct permeability was measured and the duct was perfused with activated pancreatic enzymes as before.

This paper was presented at the Meeting of the Surgical Research Society which took place in Bristol, UK, in July 1988.

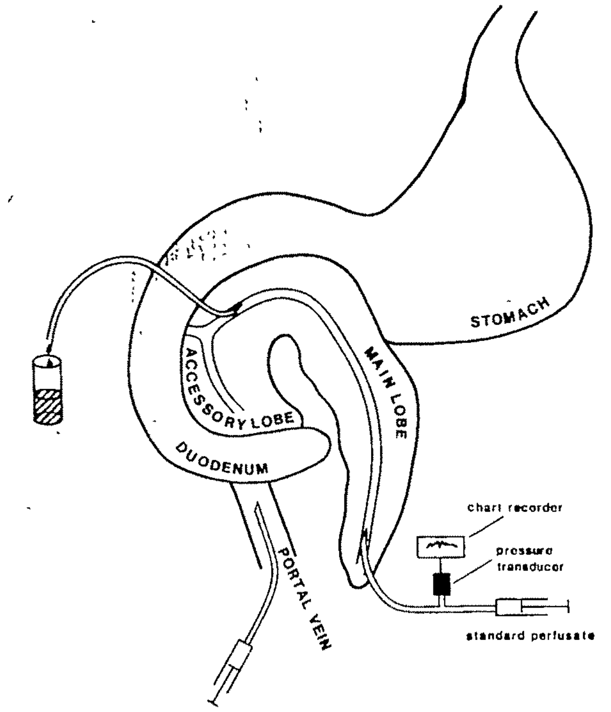

Figure 1 *Diagrammatic representation of the model used to study the effect of sodium glycodeoxycholate on pancreatic duct pressure, duct permeability and the development of acute pancreatitis. Normal saline or sodium glycodeoxycholate was perfused through the duct via the cannula in the tail of the gland and ductal pressure measured via the transducer connected to this cannula Large molecular weight fluoresceinated dextrans were perfused along the duct and portal venous blood was sampled for its dextran content via a cannula placed in the portal vein just distal to its origin from the superior mesenteric and splenic veins Then, in a separate group of cats, activated pancreatic enzymes were perfused along the duct*

The results were analysed using Fisher's exact test for nominal data and the Mann–Whitney *U* test for ordinal data. Statistical significance was assumed where $P < 0.05$.

Results

Perfusion of the pancreatic duct with sodium glycodeoxycholate, intragastric instillation of ethanol and pancreatic secretion against ductal obstruction of 50 per cent or greater all led to a significant increase in pancreatic duct pressure (*Table 1*). In experiments 1 and 3 the pressure rise was seen within a few minutes of introducing sodium glycodeoxycholate or secretagogue and reached a peak by 10 min. In each group the pressure then gradually fell to a plateau level above basal pancreatic duct pressure which was sustained throughout the hour of pressure measurement. In experiment 2 the pressure rise occurred within 10 min of ethanol instillation into the stomach and was sustained throughout the hour of pressure measurement. Mean(s.e.m.) serum ethanol levels 1 h after ethanol administration were 258(24) mg/dl.

Overall, ductal permeability to 20 000 molecular weight dextran molecules was increased in 22 of 29 experimental animals compared with only two of 22 control animals ($P < 0.01$; *Table 1*). When activated pancreatic enzymes were perfused along the pancreatic duct, acute pancreatitis developed within 24 h in 24 of 29 experimental animals compared with only three of 22 control animals ($P < 0.01$). In most cases the pancreas showed changes of oedematous pancreatitis but some animals in the secretion against obstruction group developed haemorrhagic pancreatitis. The inflammatory scores were significantly higher in each experimental group compared with the respective control group (*Table 2*).

Discussion

Reflux of bile into the pancreatic duct, alcohol ingestion and secretion against pancreatic duct obstruction have all been implicated in the pathogenesis of acute pancreatitis. The experiments described in this paper were designed to simulate

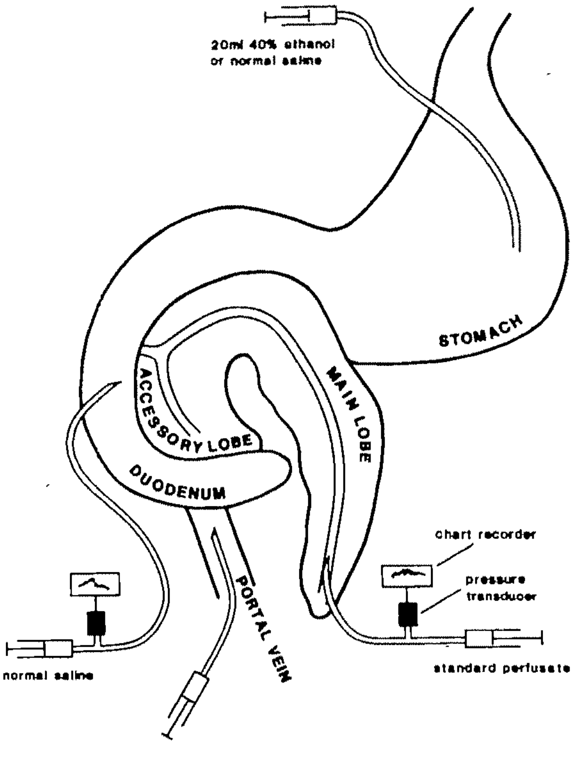

Figure 2 *Diagrammatic representation of the model used to study the effect of alcohol Ethanol or saline was instilled into the stomach as shown Intraduodenal pressure was also measured in all animals and remained constant throughout the procedure*

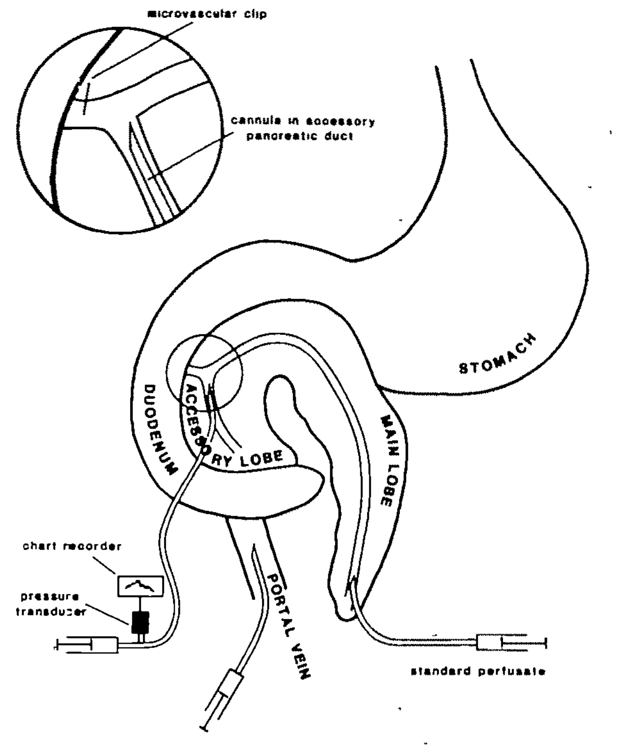

Figure 3 *Diagrammatic representation of the model used to study the effect of pancreatic duct obstruction. The microvascular clip (shown in the insert) was placed with the aid of a dissecting microscope and its position was confirmed by a second observer*

these events in a cat model. Thus, bile reflux was simulated by ductal perfusion with a bile salt at a concentration similar to that seen in human gallbladder bile[3]. Ethanol administration was simulated by intragastric instillation of ethanol resulting in similar serum concentrations found after acute alcohol intoxication in man[4]. Pancreatic secretion against partial or complete pancreatic duct obstruction, caused by gallstone impaction at the ampulla of Vater, was simulated by means of secretion against an obstructing microvascular clip. All of these events led to an increase in pancreatic duct pressure and an increase in ductal permeability to large molecules. The mechanism underlying ductal hypertension following duct obstruction with active pancreatic secretion is obvious. However, the mechanism by which pancreatic duct pressure rises following ductal perfusion with sodium glycodeoxycholate or intragastric ethanol administration is less clear. Most studies of the effect of ethanol on the sphincter of Oddi have shown an increase in sphincteric tone[5–9] and this, coupled with an increase in pancreatic secretion following ethanol, might lead to an increase in ductal pressure. The effect of sodium glycodeoxycholate on ductal pressure cannot be explained as easily because the sphincter of Oddi was excluded from the system in experiment 1 by placing a cannula in the pancreatic duct proximal to the sphincter. It is possible that the pressure increase seen with sodium glycodeoxycholate perfusion was due to partial duct obstruction by cellular debris shed from the luminal cells as a result of the detergent action of the bile salt, or alternatively by ductal spasm.

In all three models an increase in pancreatic duct permeability to large molecules was seen following the pancreatic duct insult. The mechanism by which the cat pancreatic duct becomes permeable to large molecular weight molecules is uncertain. The effects of sodium glycodeoxycholate, ethanol and pancreatic duct obstruction on pancreatic duct pressure suggest that ductal hypertension may be a common factor leading to the increase in ductal permeability.

Dextran molecules of molecular weight 20 000 were used as the markers of duct permeability as their size approximates that of several pancreatic enzymes including trypsin (23 000), chymotrypsin (25 000) and phospholipase A (14 000). Previous work has shown that the dextran molecules are not physically or chemically altered when they cross the pancreatic duct and vascular barriers[10]. When activated pancreatic enzymes were perfused along a permeable pancreatic duct, acute pancreatitis resulted in the majority of animals. This suggests, but does not prove, that pancreatic enzymes escaped from the duct into the surrounding parenchyma and initiated events leading to the development of acute pancreatitis. It is important to point out that in these experiments activated pancreatic enzymes were artificially introduced into the permeable pancreatic duct. We have also previously shown that the presence of inactive enzymes within a permeable duct does not lead to acute pancreatitis. However, there is evidence that under certain circumstances activated pancreatic enzymes can be found in the ductal system during an attack of pancreatitis[11–14]. Moreover, ethanol has been shown to result in autoactivation of pancreatic enzymes[15] and Grant *et al.*[16] have suggested a mechanism by which enterokinase, carried in bile, might bring about intraductal activation of zymogens.

If ductal hypertension is important in the pathogenesis of human acute pancreatitis then early ductal decompression may be beneficial in selected cases. Stone *et al.*[17] operated on 36 patients with acute pancreatitis within 73 h of admission to decompress the common bile and pancreatic ducts. They noted inflammation of the ampulla in 89 per cent of cases, with stones in the common bile duct and duodenum in 75 and 31 per cent respectively. They described a sudden 'gush' of pancreatic juice when the ampullary sphincter was divided at sphincterotomy in all patients, suggesting that ductal hypertension was present. This phenomenon was not seen in patients who underwent operation at 3 months. Neoptolemos *et al.*[18] compared early (within 72 h) endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy with conventional treatment for severe acute pancreatitis. The incidence of complications of pancreatitis was 24 per cent with a 4 per cent mortality rate in the ERCP group compared with 61 per cent with an 18 per cent mortality rate in the group treated conservatively.

These studies also demonstrate that the permeable duct cat model of acute pancreatitis has a number of advantages over conventional animal models of the disease. Acute pancreatitis can be produced by physiological manipulations which closely simulate events thought to be important in the pathogenesis of human acute pancreatitis. Furthermore, high pancreatic duct pressures are not required to produce the disease. The peak pancreatic duct pressure generated in the cat pancreatic duct by sodium glycodeoxycholate, ethanol and pancreatic secretion against a > 50 per cent obstruction remained within the physiological range. Aho *et al.*[19] showed that the rat pancreatic duct ruptured at a pressure of 82 mmHg and studies in several species[20] have shown that the maximum pressure generated in the completely obstructed pancreatic duct rarely exceeds 32 mmHg. Despite these observations, several animal models of acute pancreatitis involve the retrograde injection of various substances into the pancreatic duct at pressures up to 140 mmHg. Severe pancreatic damage results from these manoeuvres regardless of the substance injected. It seems unlikely that pressures in this range are ever generated in the human pancreatic duct and the results from experiments using high pressure models should be interpreted with caution.

Haemorrhage is a life-threatening complication in pancreatic disease. Twenty-five patients with this complication are described; 15 had major bleeding, nine had minor bleeding and one patient had a pseudoaneurysm identified at operation. Of the 15 patients with major bleeding, six presented with this complication and in nine cases it followed pancreatic resection. Of the six patients who presented with major bleeding, five underwent resection with one death while the patient managed conservatively died. The nine patients who had major bleeding after pancreatic resection were managed by ligation of the bleeding artery in six cases with one death, and one patient who rebled after ligation of the bleeding artery was successfully managed by further resection. Three patients with postresection major bleeding were managed conservatively with one death. All minor haemorrhages were managed conservatively without mortality. Deaths after major bleeding were a result of sepsis in three cases and respiratory failure in one. The severity of the underlying pancreatitis was an important factor in two patients. Pseudocysts and pancreatic fistulae were important underlying factors leading to the complication. It is recommended that patients with sepsis, a pancreatic fistula or severe underlying pancreatitis should have their haemorrhage treated by pancreatic resection, while those patients with bleeding following pancreatic resection without such complications can be managed by ligation.

Keywords: Haemorrhage, resection, pseudocyst

Haemorrhage is an unusual complication of pancreatic disease, but one which is associated with high morbidity and, indeed, mortality rates when it does occur[1]. Haemorrhage as a complication of pseudocyst formation is well documented[2–4]. A few reports mention haemorrhage in acute pancreatitis without pseudocyst formation[5], and as a result of chronic pancreatitis[1,6,7]. Recently Trede and Schwall have highlighted haemorrhage as a complication of pancreatic surgery with 16 instances in 285 resections[8]. A recent experience with haemorrhage following pancreatic surgery prompted review of this complication in 341 patients who had pancreatic surgery between 1976 and 1987.

Patients and methods

Between 1976 and 1988, 341 operations were performed for benign and malignant pancreatic disease. Twenty-five patients had haemorrhage as a complication of their pancreatic disease. These patients were identified on a retrospective study of the pancreatic surgery database maintained on a prospective basis The haemorrhage was either major and life threatening or minor and almost inconsequential

A major bleed has been defined as one in which the patient presents with a drop in haemoglobin concentration >4 g/dl, has a transfusion requirement of >4 units of packed cells at resuscitation and has evidence of peripheral circulatory impairment. A minor bleed has been defined as one where the patient shows evidence of haemorrhage with minimal or a transient circulatory embarrassment.

Fifteen patients had had a major haemorrhage and nine suffered a minor bleed (*Figure 1*). One patient was noted at operation to have a large pseudoaneurysm as the cause of a mass in the head of the pancreas, and haemorrhage from it was responsible for the sudden clinical deterioration. This patient's bleed is classified as an incidental bleed and he will not be considered further.

Results

Presentation

Major haemorrhage. This group of patients has been subdivided according to whether the patients had a major pancreatic resection or not. In the non-resection group (six patients), all of the patients had acute pancreatitis (four alcohol-related, two gallstone-related), with pseudocyst development in four; one patient had a pancreatic phlegmon associated with massive bleeding following its rupture into the duodenum, and in one patient the pancreatitis occurred following transduodenal sphincterotomy for the extraction of a common bile duct stone complicated by a duodenal perforation and a peripancreatic abscess. In the four patients with pseudocysts, one bled 14 days after cystgastrostomy had been performed, one bled 27 days after an episode of acute pancreatitis, the third patient bled from a pseudoaneurysm 7 months after a pancreaticojejunostomy with choledochojejunostomy Roux-en-Y for alcoholic pancreatitis, and haemorrhage in the fourth

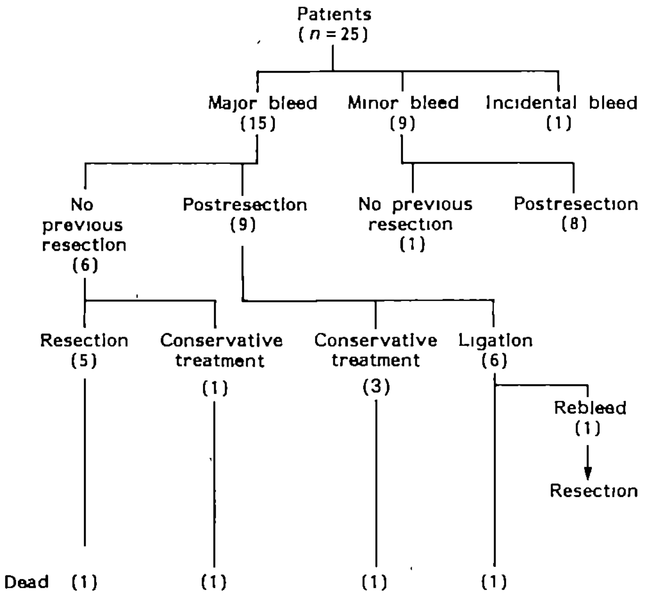

Figure 1 *Analysis of 25 patients with haemorrhage*

0007-1323/89/080863-04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

patient occurred after percutaneous drainage (third day after drainage). The first patient was transferred from another hospital with uncontrolled bleeding and the next two were admitted from home on an emergency basis with profuse bleeding. All patients were in pain and two were in respiratory failure.

Nine patients had major postresection haemorrhage. Five of these patients had neoplastic disease and four patients had chronic pancreatitis. The operations previously undertaken in these patients included pancreaticoduodenectomy in two patients, resection of an insulinoma from the head of the pancreas in one patient, a duodenum-preserving resection completing a total pancreatectomy in another, and distal pancreatic resection in five patients. All patients had pain and all had a haematemesis and/or melaena; four of the nine patients had evidence of intra-abdominal sepsis. A pancreatic anastomotic leak identified by either fistula formation or prolonged drainage from a pancreatic drain left *in situ* at operation was present in seven patients. Three of these patients bled through their anastomotic splint drains. A preliminary warning bleed preceded a major haemorrhage by 6 h–10 days in all patients. Major haemorrhages occurred 7–30 days after surgery (median 14 days).

Minor haemorrhage. One patient presented with minor bleeding 2 days after cystgastrostomy, the blood passing along the gastrostomy tube. Eight patients presented after resection, with pain in six, haematemesis or melaena in five, and anastomotic splint haemorrhage in three patients. Three patients had evidence of a pancreatic anastomotic leak. This group includes one patient who had a duodenal leak following a duodenum-preserving resection. Bleeding occurred from 1 to 20 days after the operation.

Investigations

With the co-operation of the endoscopist and radiologist, a multidisciplinary approach was possible in the management of these patients, who were often desperately ill. In the 15 patients with major haemorrhage, upper gastrointestinal endoscopy was undertaken in six patients, ultrasonography in five, computed tomographic (CT) scanning in three and selective arteriography in three patients. In the nine patients with minor haemorrhage, endoscopy was undertaken in two, ultrasonography in three and CT scanning in two patients. It was decided in a number of patients with minor haemorrhage not to investigate further. In some, with major exsanguinating haemorrhage, a decision to operate early was taken after discussion with the radiologist.

Of the three patients in whom arteriography was performed, the site of bleeding was demonstrated in only one patient; embolization was tried, but it failed to control the bleeding. Endoscopy performed in eight patients was contributory in one patient, in whom it revealed a duodenal perforation through which a pancreatic phlegmon had ruptured. Endoscopy diagnosed a bleeding gastric ulcer in one patient who subsequently had a massive haemorrhage from an underlying pseudoaneurysm, and endoscopy was thus misleading

Management

The management of the patients followed accepted practice, with replacement of blood volume as clinically indicated; a decision to operate was made on the grounds of failure to control bleeding by conservative measures. At operation, the easiest technique to control haemorrhage was used, and resection was performed only if it was considered necessary to prevent further bleeding by gaining better control of the bleeding vessel, or by overcoming pancreatic leakage when this was considered to be the underlying cause of bleeding. Jaundice and diabetes added to the difficulties in management.

Major haemorrhage (*Figure 1*). There were six patients who had not previously had resection at the time of haemorrhage; four were managed by initial resection, one by ligature and one conservatively.

In one patient, bleeding from rupture of the splenic artery into a pseudocyst was controlled by distal resection. This patient is well 6 years after resection. The second patient had a pseudocyst treated by a pancreaticojejunostomy and underwent an emergency pancreaticoduodenectomy with good result. The third patient who had a duodenal perforation from acute pancreatitis underwent necrosectomy and salvage pancreatectomy with repair of the duodenal and transverse colonic perforations. He made a rapid recovery and is well 7 years later. The fourth patient, who bled after a transduodenal sphincterotomy, had necrotic pancreatitis with abscess formation; a salvage pancreaticoduodenectomy was undertaken to control a bleeding left gastroepiploic artery but he died 3 h after operation. In the fifth patient, haemorrhage occurred after cystgastrostomy; initially the bleeding vessel was ligated, but rebleeding occurred on day 15. This was controlled by a pancreaticoduodenectomy and the patient is well 7 years later. The sixth patient had a pseudocyst, which was managed conservatively on account of her age (80 years) and respiratory failure; she developed a haemorrhage from which she exsanguinated 35 min later. Transfusion requirements in these six patients ranged from 4 to 28 units.

Of the nine patients who had had previous resection, three were treated conservatively, two of whom did well (one had had a duodenum-preserving completion resection and the other a distal pancreatic resection for an apudoma), although the third patient died in the sixth week after bleeding, from a further haemorrhage. In this last patient an initial episode of bleeding was attributed to a gastric ulcer identified on endoscopy. He was managed medically and surgery was not considered during the subsequent bleed because he had undergone non-curative resection for an aggressive pancreatic carcinoma. This decision was taken despite his age (52 years).

The bleeding artery was ligated in the six patients in whom haemorrhage was surgically controlled. The site of bleeding was the splenic artery (two patients), the gastroduodenal artery (one patient), the inferior pancreaticoduodenal artery (one patient) and the hepatic artery (two patients). Both patients who bled from the hepatic artery had further haemorrhage. This was fatal in one patient, who was 70 years old, jaundiced and who had an aggressive carcinoma. The other patient also with neoplastic disease had a further ligation with distal resection as he was found at operation to have a small retropancreatic abscess. This patient survived. Two patients with a splenic artery bleed required reconstruction of their pancreaticojejunal anastomosis as these had been opened to gain access to the site of haemorrhage. The transfusion requirement was 4–42 units.

Minor haemorrhage. The single patient with minor haemorrhage who had not had a resection experienced bleeding after cystgastrostomy and was treated conservatively and successfully for presumed suture line haemorrhage. Eight patients had a minor bleed following resection, and all were managed conservatively and successfully. Their site of bleeding remains unknown. All minor haemorrhages were regarded as potential warning bleeds and the patient was watched with care as an in-patient for at least 7 days.

The last patient in our series underwent a difficult pancreaticoduodenectomy for a pseudoaneurysm which was identified at operation, having presented preoperatively as a mass in the head of the pancreas. Haemorrhage from this was contained within the leaves of the transverse mesocolon and was responsible for sudden clinical deterioration in this patient; he was cured by a pancreaticoduodenectomy.

Discussion

This paper describes haemorrhage in relation to pancreatic disease. Massive haemorrhage in severe pancreatitis is well documented. Stroud *et al.*[5] described 15 cases with a mortality

Table 1 *Summary of previous descriptions of haemorrhage associated with pancreatic disease*

				Haemorrhages (*n*)					
Operation	Reference	*n*	Mortality (%)	Total	Gastro-intestinal	Intra-abdominal	Mortality (%)	Pancreatic leak (%)	Sepsis (%)
Pancreaticoduodenectomy	13	88	19	16	12	4	56	14	23
Total pancreatectomy	14	83	4·8	4	2	2	50	—	7/83
Pancreaticoduodenectomy	15	279	12·5	31	NR	NR	58	20	57
Pancreaticoduodenectomy	16	103	10·6	6	5	1	—	14·5	—
Various	17	177	6	10	5	5	—	6	7
Pancreaticoduodenectomy	8	285	3·1	16	12	4	6·25	8·8	2·4

NR, not recorded

rate of 53 per cent, the patients with pseudocysts showing the highest survival rates. Their transfusion requirements of 8–177 units highlight the magnitude of the problem.

Chronic pancreatitis as a cause of gastrointestinal bleeding is well described[6,7]. Bleeding through the pancreatic duct is a particularly difficult diagnostic problem[9–11] Investigations can be inconclusive[12] but, despite false negative results, coeliac axis angiography is recommended[7] although the authors do accept that it is often non-contributory. It is documented that 10 per cent of patients with chronic pancreatitis have associated pseudoaneurysms[1].

Description of postresection haemorrhage is inadequate. The reported incidence varies from 5 to 19 per cent[13,14] and in our experience it was 9·5 per cent in patients with pancreatitis and 7·5 per cent in patients with neoplasms. The mortality rates range from 6 to 58 per cent (*Table 1*). In most series, haemorrhage is mentioned only in passing but, on close study, the incidence and risk of mortality from postresection bleeding in many reports reflect closely the mortality rate of the series.

Jordan[18] reported seven deaths in 16 patients with pancreatic fistulae that complicated 63 pancreaticoduodenectomies. In four of the seven cases it was due to postresection haemorrhage, the gastroduodenal artery being the usual source. Trede and Schwall[8] highlight the occurrence of postresection complications around the pancreatic anastomosis. Haemorrhage in this series of 285 pancreaticoduodenectomies was the second most frequent complication occurring in 16 (5·6 per cent) cases with one death, which they attribute to delayed operation. In the series reported by Trede and Schwall the increased mortality rate following haemorrhage and pancreatic leaks in the jaundiced patient is well demonstrated. All of their patients had endoscopy at the onset of bleeding. The severity of bleeding in their patients is not documented. Four patients were managed with endoscopic laser or injection treatment. Of the remaining 12 patients, eight patients with gastrointestinal bleeding and four patients with retroperitoneal haemorrhage required ligation of the bleeding vessel. The management of patients at risk of recurrent haemorrhage is difficult and many techniques have been tried, such as continuous irrigation of the operation site via catheters placed at the time of operation[15]; of the techniques described, completion resection appears to be the logical choice[19]. The presence of sepsis, jaundice and glandular friability are important factors which are responsible for the increased risk of mortality following pancreaticoduodenal resection[15].

Our experience favours early resection in non-resected patients who develop major bleeding as four of the five patients so treated achieved good results. Haemorrhage in patients with pseudocysts is described as spontaneous or postoperative (i.e. following drainage). Internal drainage does not afford any protection from bleeding, although there are suggestions that pseudocystjejunostomy Roux-en-Y may be associated with a lower incidence of stomal suture line bleeding. Even if this were true, the operation will not prevent haemorrhage from an underlying pseudoaneurysm. This is also apparent from series reporting as many preoperative as postoperative cases of haemorrhage[2,3]. Frey *et al.*[20] recommended primary excision of the cyst, and suggest that ligation of the bleeding vessel in the presence of pancreatitis is unlikely to succeed. Acute pancreatitis with haemorrhage managed conservatively may be associated with a 100 per cent mortality rate[21]. Surgery, which has by some been considered ill advised, will with adequate intensive care support improved survival figures[20–23]. We have not been able to evaluate the role of embolization, which has been well documented in a complementary capacity[24]. The literature is now replete with reports of successful embolization of major arterial bleeding and of several pseudoaneurysms[25–28]. This is probably the way forward in reducing the risk of mortality from haemorrhage in these gravely ill patients, but the skill required for embolization is considerable.

The occurrence of warning haemorrhages in postresection patients has not been described previously. These are similar to minor haemorrhages but preceded major bleeding by 6 h–10 days. They occurred in all postresection major bleeds, and serve to emphasize the importance of watching carefully all episodes of bleeding, however small, in the postresection patient. In our experience, postresection bleeds in chronic pancreatitis (four patients) were safely managed with ligation. Of the five patients in the neoplastic group who had major bleeding, two deaths were due to 'inadequate' surgical management. Early ligation is the treatment of choice in the absence of sepsis or fistula formation, and resection should be considered if either is present. Investigations in the presence of major haemorrhage are often unhelpful and should be undertaken only after close consultation with the appropriate specialist, who must have experience in these techniques The difficulty with endoscopy and imaging is mainly related to the fact that haemorrhage occurs near the pancreaticojejunal anastomosis and passes down the jejunal loop. Thus endoscopy is often negative while ultrasonography or CT scanning show no abnormality unless associated with an abscess or a pseudocyst. Angiography may well be the only investigation that will elucidate the source of bleeding. Unfortunately, the bleeding is often massive and intermittent, and thus missed at angiography. The use of angiography in our hands proved disappointing, and it was used sparingly. Early resuscitation and operation will be indicated in many patients, especially in those with underlying sepsis or fistula formation. Angiography at the warning-bleed stage may identify patients with vascular lesions amenable to embolization.

We recommend that major non-resection haemorrhage should be managed by early resection, while major postresection bleeding in patients with underlying chronic pancreatitis can be treated with ligation and, if need be, with reconstruction of a failed pancreatic anastomosis. However, in the presence of sepsis, abscess formation or an established pancreatic fistula, resection of the remaining pancreas should be considered

Endoscopic management of inoperable cholangiocarcinoma using iridium-192

We report a well tolerated endoscopic technique of administering intraluminal radiotherapy to 14 patients with inoperable cholangiocarcinoma, in which the iridium-192 wire source was inserted down a nasobiliary catheter placed within a previously inserted endoscopic biliary prosthesis, thus allowing bile flow to continue during treatment. Radiotherapy was commenced 2 weeks after biliary decompression, when the median serum bilirubin level had fallen from 213 to 34 μmol/l. A total radiation dose of 6000 cGy at 0·5 cm from the source was administered over a median of 85 h (range 77–116 h). In four patients there was a transient increase in serum bilirubin during iridium treatment and, in two cases (14 per cent), this was associated with mild cholangitis. Both cases resolved rapidly once the iridium wire and nasobiliary catheter were removed. The median hospital stay after treatment was 2·5 days (range 0–28 days). The late complications associated with stent blockage were minimized by routinely changing stents at 4–6-monthly intervals; ten of the patients have so far undergone from one to five (median three) stent changes. Five patients have died at 3·6–8·2 months (median 4·8 months) following iridium treatment; four had extensive type III hilar lesions at diagnosis. Nine patients are still alive at 5·4–31·0 months (median 16·4 months). The overall median survival after iridium therapy is 10·5 months. This technique of endoscopic biliary decompression before internal iridium administration minimizes complications by allowing biliary drainage during treatment. The role of this treatment in patients with inoperable cholangiocarcinoma awaits the results of randomized, controlled trials.

Keywords: Cholangiocarcinoma, iridium-192

Cholangiocarcinoma is a relatively slow-growing tumour which rarely metastasizes[1]. Complete surgical resection is possible in only 10–20 per cent of cases[2–4] and preliminary results of hepatic transplantation are disappointing, with death usually occurring in the first year. Thus the majority of patients are managed palliatively with relief of biliary obstruction either surgically or by endoprosthesis insertion. Unfortunately, the survival of patients undergoing palliative surgical bypass (8–10 months)[3–5] or transhepatic prosthesis insertion (3–9 months)[4–6] is limited, predominantly because of local extension of the tumour resulting in further biliary obstruction, recurrent episodes of cholangitis, liver failure, sepsis, haemorrhage and death.

Although these tumours were originally considered to be resistant to radiotherapy, more recent studies have suggested that this is not the case[6–9]. Since 1981, a number of groups have reported the use of internal radiotherapy using iridium-192 inserted surgically or transhepatically in patients with bile duct carcinoma[10–17]. The morbidity and mortality rates associated with percutaneous endoprosthesis insertion appear to be higher than that experienced with the endoscopic route[18]. In a recent study of 24 patients with malignant biliary obstruction, treatment with iridium-192 inserted via an endoscopically placed nasobiliary tube with subsequent endoprosthesis insertion was associated with a 30 per cent incidence of early cholangitis[17]. This high incidence is possibly due to poor biliary drainage during the period of intraluminal irradiation. The present study reports the endoscopic administration of internal iridium-192 radiotherapy in 14 patients with inoperable cholangiocarcinoma who had undergone prior biliary decompression by endoscopic endoprosthesis insertion.

Patients and methods

Patients

Fourteen patients (ten men, four women) aged 41–80 years (median 60 years) with cholangiocarcinoma involving the bifurcation of the bile duct, seen between February 1986 and June 1988, were deemed inoperable on the basis of laparotomy (four patients) or various imaging techniques (ultrasound, computed tomography (CT) scan, arteriography: eight patients), or due to age and poor general medical condition (two patients). The initial diagnosis was based on the characteristic appearances of cholangiocarcinoma on endoscopic retrograde cholangiopancreatography (ERCP) with an abnormal cholangiogram but a normal pancreatogram, a normal upper gastrointestinal endoscopy, and no obvious clinical evidence of a distant primary neoplasm. Nine patients had type III hilar lesions based on the Bismuth classification[19]. In five of these patients there was extensive involvement of the intrahepatic ducts (recently classified as type IV)[4]. The remaining five patients had type II lesions. The diagnosis was confirmed histologically in ten patients: in four patients at prior laparotomy, in two patients by cytological examination of tumour brushings, in one patient by percutaneous biopsy and in three patients at post-mortem examination.

Jaundice had been present for between 2 and 10 weeks (median 5 weeks) at the time of diagnosis, when the median serum bilirubin was 213 μmol/l (range 27–415 μmol/l).

Methods

At initial ERCP a 10 Fr prosthesis (Cotton–Leung biliary stent, Wilson–Cook Medical Incorporated, Winston-Salem, North Carolina,

0007–1323/89/080867–03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

USA) was inserted through the tumour with its distal end protruding 1–2 cm into the lumen of the duodenum. All patients received antibiotics (amoxycillin and gentamicin) intravenously before and for 48 h after endoprosthesis insertion and, provided the bilirubin level was falling satisfactorily, were discharged home after 48–72 h. Patients were readmitted approximately 2 weeks later once the serum bilirubin had fallen and their general medical condition improved. A second examination using ERCP was performed and the biliary prosthesis was cannulated with a 6 Fr Teflon® (E.I. du Pont de Nemours and Company, UK) guiding catheter (Meadox-Surgimed, Stenløse, Denmark), which was positioned at the top of the prosthesis and the upper and lower limits of the stricture were defined radiologically. The endoscope was then removed and the Teflon catheter was rerouted through the nose and allowed to drain freely. A length of iridium-192 wire long enough to overlap the upper and lower margins of the stricture by a minimum of 1 cm was loaded into the tip of a standard radiological Teflon-coated movable-core guidewire (35×10^{-3} inch diameter; Tefcore®, William Cook Europe, Bjaeverskov, Denmark; *Figure 1*). This was inserted into the nasobiliary catheter and the iridium source was positioned at the level of the stricture under radiological control (*Figure 2*). The nasobiliary catheter was then connected to a sealed bag system to allow for bile drainage around the guidewire. Patients were nursed in a side room and surrounded by lead screens. Intravenous antibiotics were administered for the duration of the iridium-192 therapy which ranged from 77 to 116 h (median 85 h), depending on the length and activity of the iridium wire used. All patients received a total dose of 6000 cGy at 0·5 cm from the source. Once the radiotherapy was completed, the iridium wire and Teflon catheter were removed under fluoroscopic control, leaving the endoscopic stent *in situ*.

Results

Endoscopic insertion of the prosthesis was completely successful on the first occasion in 11 of the 14 patients. In the remaining three patients, the stricture was too tight to dilate fully; a nasobiliary catheter was inserted in one patient and in the other two patients a percutaneous transhepatic catheter was left *in situ*. In all three patients it was subsequently possible to insert an endoscopic prosthesis. All patients received intraluminal radiotherapy with iridium-192 and most patients were discharged home within a few days of completing this treatment; the hospital stay after the procedure ranged from 0 to 28 days (median 2·5 days). The median serum bilirubin level was 213 μmol/l (range 27–415 μmol/l) before biliary decompression and fell to 34 μmol/l 2 weeks after stent insertion and to 24 μmol/l by the time of discharge following iridium treatment.

There were no deaths within 30 days and few early complications following iridium therapy. In four patients there was a transient increase in serum bilirubin during iridium treatment, and in two cases (14 per cent) this was associated with mild cholangitis despite prophylactic antibiotics. Both cases resolved rapidly once the iridium wire and nasobiliary catheter were removed. One patient experienced mild nausea while the iridium source was *in situ*. One patient, in whom the iridium wire and nasobiliary tube were removed without fluoroscopic control, was readmitted 4 days later with increasing jaundice and cholangitis due to dislodgement of the prosthesis.

In order to avoid late complications associated with stent blockage (particularly recurrent jaundice and cholangitis), endoprostheses were changed routinely at intervals of 4–6 months. Ten of the patients have so far undergone from one to five (median three) stent changes and there have been only two episodes of cholangitis and three episodes of jaundice due to blocked endoprotheses. In one patient with a type III lesion, it was necessary to insert stents into both hepatic lobes to provide adequate biliary drainage and relieve cholangitis.

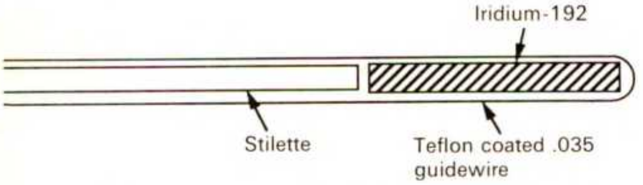

Figure 1 *Schematic representation of an iridium-192 wire within a movable-core guidewire. The guidewire stilette is reinserted until the length of iridium wire is located at the distal end of the guidewire*

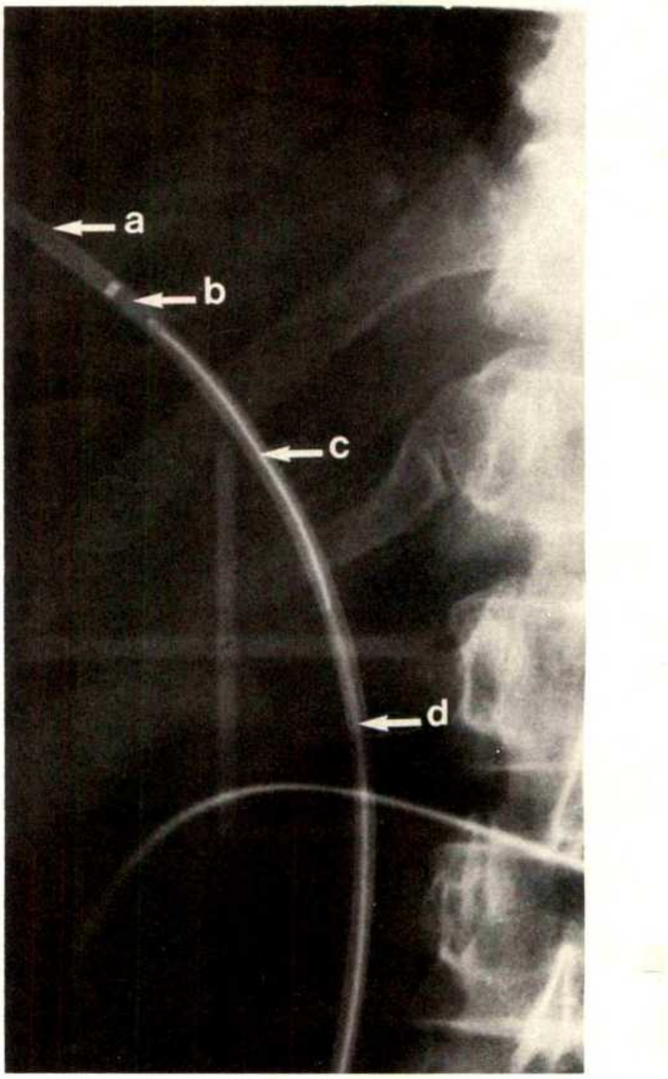

Figure 2 *Radiograph of an iridium-containing guidewire inserted into a nasobiliary catheter which has been inserted into an endoscopic stent. A radio-opaque marker at the distal tip of the nasobiliary catheter allows precise placement of the iridium wire across the malignant stricture. Labelled arrows indicate the endoscopic stent* (*a*), *the nasobiliary catheter with distal radio-opaque marker* (*b*) *and the iridium-192 wire* (*c*) *within the movable-core guidewire* (*d*)

Five patients have died at 110–249 days (median 146 days) after iridium treatment. Four of these patients had type III cholangiocarcinomas with extensive involvement of the intrahepatic bile ducts at diagnosis. Nine patients are still alive at 165–942 days (median 498 days). The overall median survival after iridium therapy is 318 days (10·5 months).

Discussion

A number of studies have suggested that the survival of patients with biliary obstruction due to cholangiocarcinoma may be improved by using internal radiotherapy in addition to palliative biliary decompression[14-16]. However, substantial morbidity and mortality rates have been reported with this technique, particularly related to the percutaneous transhepatic approach[14] and also to the high incidence of early cholangitis, ranging from 30 to 40 per cent[10,14,17]. In the present study, the 30-day mortality rate was zero and the incidence of cholangitis associated with insertion of the iridium-192 wire was 14 per cent. This figure is similar to that reported with the insertion of an endoscopic endoprosthesis alone[18]. The substantially lower incidence of cholangitis in the present study is possibly related to the policy of relieving the biliary obstruction by endoprosthesis insertion before placement of the iridium-192 wire. In this way biliary drainage is maintained around the nasobiliary tube and iridium-192 wire during the course of treatment. It is also possible that the improvement in the general condition of patients observed when jaundice is alleviated may be associated with a lower incidence of complications. The problem of impaired bile flow during iridium-192 treatment may, in the future, be solved by the use of high-dose-rate, remote afterloading devices which can deliver the same dose of iridium-192 in a single treatment over minutes[20].

The median survival time in this series compares favourably with that of patients undergoing palliative surgery and is similar to that reported following radical resection[3–5]. However, a definite role for internal iridium-192 in the treatment of cholangiocarcinoma has not been confirmed in a randomized controlled trial. Iridium-192 emits predominantly γ radiation, which causes an intense but localized radiation field resulting in minimal radiation damage to the surrounding organs. Radiation doses in excess of 4000 cGy have been reported to improve survival in patients receiving external radiotherapy[7,9], but the optimal radiation dose and treatment regimen for cholangiocarcinoma has yet to be determined. Indeed, it is possible that a combination of internal and external radiotherapy, which provides a more uniform radiation field[11,21], might offer the best chance of long-term survival. Clearly, all future trials should stratify patients according to the site and extent of the tumour as survival is progressively worse in patients with extensive intrahepatic spread[4]. This point is highlighted in the present study where four of five patients with extensive type III (type IV) hilar strictures died of their disease 4–8 months after treatment, whereas nine patients with type II and less extensive type III lesions are still alive at a median of 16·4 months. This compares favourably with the Middlesex Hospital experience of stenting alone for cholangiocarcinoma, where the median survival time for type II and type III lesions was 4 and 3 months respectively[22].

The results of the present study are encouraging. The technique was well tolerated and associated with an acceptably low complication rate. In addition, a policy of routinely changing stents every 4–6 months has minimized the long-term complications of stent blockage, particularly recurrent jaundice and cholangitis[16]. A randomized, controlled trial comparing endoscopic stent insertion with or without radiotherapy has recently been set up to assess our initial impression that survival in patients with inoperable cholangiocarcinoma is improved by intraluminal iridium-192.

Reconstruction of chest wall defects with homologous dura mater grafts

A. N. van Geel, T. Wiggers and A. M. M. Eggermont

Department of Surgical Oncology, Dr Daniel den Hoed Cancer Center, 301 Groene Hilledijk, 3075 EA Rotterdam, The Netherlands

Correspondence to. Dr A. N. van Geel

Resections of chest wall tumours leave the surgeon with the challenging problem of reconstructing the defect. The objectives of reconstruction of full-thickness defects of the chest wall are threefold: firstly, to provide chest wall stability in order to prevent paradoxical respiration movements or herniation of the lung; secondly, to cover and protect vital organs; thirdly, to achieve the above in a cosmetically satisfactory way. Procedures using autologous materials such as periosteal or muscular flaps, or fascia lata are tedious, time consuming, often unsightly and may provide little rigidity. Because of their simple applicability and mechanical properties, synthetic materials such as Teflon® (du Pont de Nemour Inc., UK) and Marlex® mesh (C.R. Bard Inc., Massachusetts, USA) have been used with increasing frequency in recent years. However, these non-absorbable materials have disadvantages in the face of chronic infection.

To avoid these specific disadvantages dura mater grafts have been successfully used for tympanoplasties, replacement of the tracheal wall, closure of fistulae and reconstruction of the urinary bladder[1–3]. Successful application of dura mater in the reconstruction of abdominal wall defects[4] lead to its use in chest wall defects When the size of the chest wall defect necessitated replacement of soft tissue this was done by transposition of the greater omentum, covered with split skin grafts[5].

Here we report on our experience in reconstructing chest wall defects with homologous dura mater grafts in 14 patients

Patients and methods

Methods

In 1985 and 1986 partial resections of the chest wall were performed in 14 patients. In all but two patients the resection included part of the sternum. Chest wall defects ranged from 5 × 4 cm to 12 × 18 cm (average 10 × 10 cm) Homologous dura mater grafts (Lyodura®, B. Braun A.G., Melsungen, FRG) were used The human dura mater grafts have been lyophilized, freeze-dried and are immunologically inert[6] As its maximum size is 6 × 14 cm, several grafts may have to be patched together in order to close a large chest wall defect With some tension the graft is fixed to the periosteum, perichondrium and/or fascia by a running suture with polydioxanone In five patients the dura mater graft had to be covered by a pedicled greater omentum transposition which in turn was covered with meshed split skin grafts No suction was applied to the wound or the thorax.

Patients

Of the 14 patients treated, three had primary sarcomas. The remainder had secondary tumours (nine patients with a local recurrence or retrosternal metastases of breast cancer, one patient with a retrosternal recurrence of a thymoma, and one patient with a retrosternal isolated metastasis of ovarian cancer). Two of the patients with breast cancer had ulcers associated with osteomyelitis and extensive radiologically induced necrosis which prompted resection. Median follow-up was 18 months (range 10–24 months).

Results

Chest wall repair was successful in all but one patient. In this patient a partial disruption of the graft on the medial side occurred during very high positive end expiratory pressure mechanical ventilation given during a long period of adult respiratory distress syndrome. This complication led to permanent paradoxical respiratory movements at this site. In all other patients the results were very favourable. Restoration of the stability of the chest wall by the dura mater grafts was excellent, especially when an omentoplasty was performed. Within 2–3 months the implant underwent a rigid transformation.

No paradox was observed in any of the patients; mechanical properties were very good. Two complications unrelated to the use of dura mater homografts occurred· a haemothorax in one patient and rupture of the diaphragm that was subsequently repaired with a dura mater implant in another.

Discussion

The results of reconstruction of chest wall defects with homologous dura mater grafts in the 14 patients described above have been satisfactory. Restoration of the stability of the chest wall has been excellent. The rigidity that is obtained when dura mater grafts are used in combination with transposition of the greater omentum in order to close large defects is remarkable. Moreover the absence of infectious complications is significant and underlines the ideal biological properties of these biografts. The simplicity of the surgical procedure, the chest wall stability and the resistance to infectious complications suggest that these homografts may well be superior to the synthetic materials commonly used. Complications related to the material were not observed. The risk of acquiring Jakob–Creutzfeldt disease after implantation of a dura mater allograft, which has been claimed in one case report[7], has not been substantiated in this or any other series.

After a follow-up period of 10–24 months (median 18 months), during which two patients died from widespread metastatic disease, only one local recurrence occurred.

Adverse effects of preoperative hepatic artery chemoembolization for resectable hepatocellular carcinoma: A retrospective comparison of 138 liver resections

Naofumi Nagasue, MD, Gennaro Galizia, MD, Hitoshi Kohno, MD, Yu-Chung Chang, MD, Takafumi Hayashi, MD, Akira Yamanoi, MD, Teruhisa Nakamura, MD, *and* **Hirofumi Yukaya, MD,** *Hiroshima, Japan*

*During the past 8 years we have treated 268 patients with primary hepatocellular carcinoma (HCC); total extirpation of the tumor was carried out in 138. Thirty-one of the patients with resectable HCCs had already been treated with transcatheter arterial embolization (TAE) of the liver before they were referred to us. The clinical values of preoperative TAE were retrospectively evaluated for those 31 patients and for the remaining 107 patients without TAE. There were no substantial differences between the two study groups in the clinical and histopathologic backgrounds. No differences were observed in the extent of liver resection, estimated blood loss during surgery, and operation time. During surgery, however, troublesome intra-abdominal complications relevant to TAE were encountered in 15 patients, and detection of tumors was impossible, even with intraoperative ultrasonography, in five patients in the group with TAE. Such findings were not present in any of the patients without TAE. Postoperative morbidity and mortality rates were similar in the two groups. There was no significant difference in the rate of recurrence of tumor in the liver, but the recurrence time was significantly shorter in the group with TAE. TAE did not improve the long-term survival rates in patients either with or without cirrhosis. Results of our study seem to indicate that preoperative TAE is meaningless in the treatment of resectable HCCs and therefore should be avoided, particularly in patients with advanced cirrhosis of the liver. (*S*URGERY 1989;106:81-6.)*

From the Second Department of Surgery, Shimane Medical University, and the Department of Surgery, Hiroshima Red Cross and Atomic Bomb Hospital, Hiroshima, Japan

HEPATOCELLULAR CARCINOMA (HCC) is one of the most malignant tumors in human beings, and its incidence has been increasing all over the world. The prognosis for those with HCC is usually dismal without treatment.[1,2] Because of its biological characteristics, with early intrahepatic spread and invasion of the portal or hepatic veins or a high incidence of associated cirrhosis of the liver, the resectability rate of this tumor is low.[3-5] However, hepatic resection is at present the most reliable and acknowledged method for permanent cure of patients with HCC, although liver transplantation may be preferable in selected patients.[6] Since its initial use for treatment of nonresectable malignant tumors of the liver,[7] embolization of the hepatic artery has been widely used with a great deal of evidence that this technique in combination with cytostatic drugs is a useful palliative alternative.[8-15]

During recent years in Japan, transcatheter arterial embolization (TAE) of the liver has been performed extensively not only for palliative purposes[13,14] but also as a preoperative adjuvant, even in patients with resectable HCCs, with the hope that TAE before hepatic resection may improve the survival rate.[16-19] From a surgical viewpoint, TAE before liver resection may have several disadvantages and possible benefits.

The purpose of this study was to retrospectively compare the results of hepatic resection in 31 patients with and 107 patients without preceding TAE therapy and to evaluate the genuine role of preoperative TAE in resectable HCC.

MATERIAL AND METHODS

From January 1980 to March 1986, 228 patients with primary HCC were admitted to the Department of Surgery, Hiroshima Red Cross and Atomic Bomb Hospital. From April 1986 until December 1987, another 40 patients with HCC were treated in this department. Thus a total 268 patients with HCC were serially treated during an 8-year period. Total extirpation of the tumor was carried out in 138 patients (51.5%). No preceding therapy had been given to 107 patients before liver resection, whereas the remaining 31 patients had undergone TAE at other hospitals. Results of imaging studies and liver function tests before TAE in these 31 patients were retrospectively evaluated by us, and it was confirmed that all of the tumors would have been resectable from the beginning. All of these patients were followed up by their physicians for 7 to 1245 days (130 ± 234 days) after TAE but were referred to us for liver resection because of either reelevation of the serum alpha-fetoprotein level, reenlargement of the tumor, or patient's desire.

Table II. Postoperative complications

Complication	*With TAE (n = 31)*	*Without TAE (n = 107)*

Postoperative bleeding	1	6
Upper gastrointestinal bleeding	1	3
Biliary fistula	1	2
Pancreatitis	1	1
Pneumonia	1	1
Adult respiratory distress syndrome	1	
Other	3	8

Method of TAE. TAE had been performed by the Seldinger technique in all instances. The mean interval between the diagnosis of HCC and the time of TAE was 22 days. Patients were then followed up for a mean of 130 days until liver resection. The embolization materials used were gelatin sponge cubes or powder in 12, oil contrast lipiodol in 14, and both materials in five patients. Thirty patients concomitantly had infusion chemotherapy with doxorubicin (Adriamycin) (10 to 60 mg) in 20, mitomycin C (6 to 20 mg) in eight, and a combination of the drugs in two instances.

Preoperative clinical background. There were no significant differences in clinical background between those with and without preoperative TAE. Only the time interval between diagnosis and operation was different (Table I). There were no differences in results of preoperative liver function tests including serum transaminase activities, serum bilirubin and albumin concentrations, and Bromsulphalein (BSP) test.

Preoperative associated conditions. Diabetes mellitus, esophageal varices, cholelithiasis, and gastroduodenal ulcer were the most common complications in the groups both with and without TAE; 9 and 29, 10 and

13, 1 and 9, and 2 and 5, respectively. The incidence of the varices was significantly higher in the group with TAE ($p < 0.01$), but no substantial difference was noted for other complications.

Statistical methods. Statistical comparisons for significance were carried out with unpaired Student *t* and χ^2 tests. A *p* value of less than 0.05 was considered statistically significant. All of the data in the tables are shown as actual number of patients or mean ± standard deviation. Cumulative survival rates were obtained by means of the Kaplan-Meier method.

RESULTS

Type of liver resection. Major hepatic resection was considered a resection equal to or larger than left lobectomy. Therefore left lateral segmentectomy, that is, the double segmentectomy of Couinaud,[21] was included in the group undergoing minor resection. Major resection was performed in 18 patients without TAE and three patients with TAE. There was no difference in the extent of liver resection between the groups with and without TAE.

Blood loss and operation time. The estimated blood loss during surgery ranged from 40 to 12,000 ml (1541 ± 1754) in the group without TAE and from 100 to 7100 ml (1497 ± 1977) in the group with TAE; there was no statistical difference. The operation times were also similar: 125 ± 57 minutes in the group without TAE and 123 ± 51 minutes in the group with TAE.

Intraoperative findings. Fifteen patients with TAE had such troublesome complications as severe adhesions, infarction of the gallbladder with or without perforation, liver infarction, or intrahepatic abscess formation. Intraoperative ultrasonograms showed the presence of tumor in all patients without TAE but not in five patients with preceding TAE.

Postoperative complications. There were 42 postoperative complications in 31 patients without TAE, whereas in eight patients with TAE there were only 13 complications. There were no differences in the incidence and type of complications (Table II).

Postoperative mortality. Nine patients died within 1 month and another eight died 1 to 3 months postoperatively. The cause of death was liver failure in all 17 patients. The overall hospital death rate was 13% in the group without TAE and 10% in the group with TAE. The mortality rate in the 107 patients without TAE increased according to the Child's grade (Table III).

Postoperative chemotherapy. Postoperative chemotherapy was given to 69 patients. There were no differences in the rate and method of chemotherapy between the two study groups (Table III).

‡$p < 0\ 05$
§$p < 0\ 01$

Recurrence of tumor. Although the follow-up time was significantly different, the rate of recurrence of tumor in the residual liver was similar in the two groups. The mean time of recurrence from either the time of the diagnosis of HCC or liver resection was significantly shorter in the group with TAE compared to the group without TAE (Table III).

Histopathologic comparison. There were no differences between the two groups in the type and size of HCC, incidence of daughter nodules, grade of tumor differentiation, or underlying liver disease. Tumor necrosis was found in all patients with TAE, but only in three was the necrosis so severe that histologic diagnosis of the type and Edmondson's grade of HCC was impossible (Table IV).

Cause of late death. During the follow-up period 50 patients in the group without TAE died; causes of death included recurrence of tumor in 39, liver failure in four, gastrointestinal bleeding in four, hepatitis in two, and gastric cancer in one. Eight patients in the

group with TAE died, seven of recurrence and one of sepsis. No statistical difference was seen.

Long-term survival. The cumulative survival rates after liver resection including operative deaths in the group without TAE and the group with TAE were 77% and 75% at 1 year, 57% and 62% at 2 years, 45% and 31% at 3 years, 33% and 15% at 4 years, and 27% and 15% at 5 years, respectively. There was no difference between the two groups (Fig. 1). Even when the survival rates after the diagnosis of HCC were compared, no significant difference was observed between the two study groups (Fig. 2). Thus, preoperative TAE did not influence long-term survival.

DISCUSSION

Despite marked advances in diagnostic methods and surgical techniques, the resectability rate of HCC is usually low.[3-5] This may be attributable to a high incidence of associated cirrhosis of the liver and the rapid growth of this tumor.[1,2] In Japan, where ultrasonography is used extensively, the incidence of relatively small HCCs has increased in recent years. In fact 49 of 138 patients in our current series had HCCs smaller than 3 cm. We have already shown that such small HCCs are frequently resectable, even in the presence of cirrhosis, by minor hepatic resection.[23,24] In this study the resectability rate was 51.5%. Probably this high rate can be explained mostly by this high incidence of small HCCs.

Even after total extirpation of HCC, the recurrence

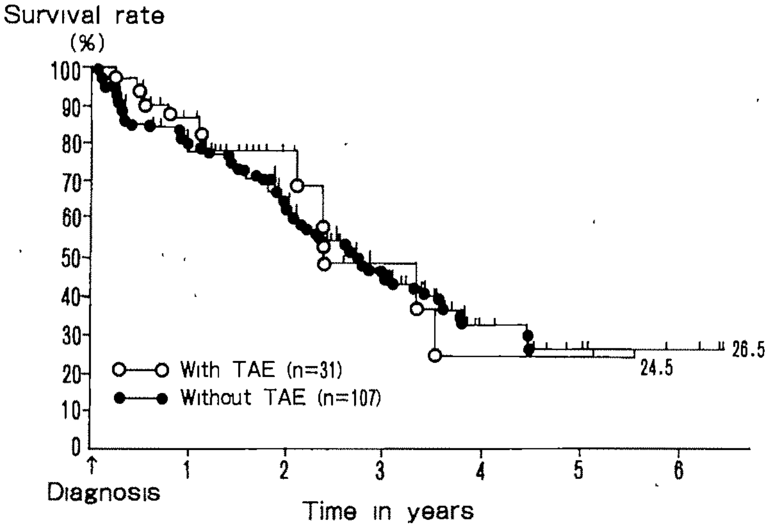

Fig. 2. Cumulative survival rates after diagnosis of HCC in the two study groups No statistical difference was observed.

rate is very high.[3-5, 24] At present, no definitive results are available concerning the role of adjuvant therapy in the treatment of HCC by resection. On the other hand, it seems that TAE of the liver in combination with cytostatic agents has become recognized as one of the best palliative methods for treating nonresectable HCC.[7, 8, 10-19] Although several groups recommend that this method be performed before hepatic resection, even in patients with resectable HCCs,[16-19] none of them has proved scientifically that preoperative TAE is useful in lowering the recurrence rate and prolonging the survival rate. A prospective controlled trial was not used in those studies.

We realize that the weakness of our study was that it was only retrospective. However, we do not assume that our results are invalid. All our patients with preoperative TAE had been treated in other hospitals before they were referred to us. That is, we were not involved at all in deciding whether or not the patient was to undergo embolization. As a result, it is likely that our patients were fairly randomized, and the two study groups were almost homogeneous as shown by the findings of our retrospective comparisons. Among various preoperative data a substantial difference was found only in the time interval between the diagnosis of HCC and surgery. It was significantly longer in the group with TAE. Also results of postoperative histopathologic comparison showed that the type and stage of HCC and underlying liver disease were comparable in the two groups. There were no differences in the extent of liver resection, operation time, and blood loss during surgery. However, various intra-abdominal complications related to TAE were observed in half of the patients who had undergone TAE. In addition, detection of tumor was impossible during surgery, even with ultrasonography, in 5 of 31 patients with TAE. This is a difficult problem in performing minor resection of cirrhotic livers for small, invisible, and unpalpable HCCs.[25]

Despite these intraoperative differences, there were no differences in the postoperative courses of the two groups. The postoperative mortality rate was 13% in the group without TAE and 10% in the group with TAE. Inasmuch as TAE has been used frequently in recent years, the postoperative follow-up time was significantly different; it was shorter in the group with TAE and longer in the group without TAE. Nevertheless, the rate of tumor recurrence in the remnant liver was similar, and the mean time until recurrence was significantly shorter in the patients who underwent embolization. The reason for this is yet to be explained.

When long-term survival of the patients was evaluated, TAE was not found to improve survival. TAE did not produce any beneficial effect in the patients overall and even adversely affected patients with advanced cirrhosis. Results of our study indicate that preoperative TAE is meaningless in the treatment of resectable HCCs and should be avoided, particularly in patients with advanced cirrhosis of the liver. We are now justified in carrying out a prospective study on this subject to determine whether the current provisional results are substantiated.

C-reactive protein and acute pancreatitis

Sir
Wilson and co-workers have presented data on the value of C-reactive protein, antiproteases and complement factors during the course of acute pancreatitis (*Br J Surg* 1989, **76**: 177–81). They have used the same design as we did some years before[1,2] and their major result is identical with our own, namely 'C-reactive protein is simple, quick to perform, provides useful clinical information and is more likely to be of value and to be adopted into routine clinical practice than multiple factor scoring systems'

In their discussion Wilson and co-workers mention that our data have been based on a study of 35 patients. Obviously, this study population was sufficient to provide comparable information. In addition, the authors mention that the cut-off level of 100 mg/l which we have shown to be predictive for pancreatic necrosis would not be adequate. In our opinion there are two reasons why the authors came to a cut-off level of 210 mg/l for a group of patients with 'severe pancreatitis': (1) they have used another assay system (Abbott TDX, Abbott Laboratories Ltd., Wokingham, Berkshire, UK) to that used in our studies (Laser nephelometry, Behring Werke AG, Marburg, FRG); (2) they have not included contrast-enhanced computed tomography in the diagnostic work-up of their patients with acute pancreatitis. This radiological modality meanwhile has been shown to be the gold standard for the staging of acute pancreatitis[3–6]. We have used this technique in our clinical trials and that is the reason we were able to speak of 'pancreatic necrosis' and why we have set our cut-off level at 100 mg/1. Obviously, the authors have not used this technique and this is one of the reasons why the study population is not comparable to ours and why the authors have based their study on a rather superficial definition of 'severe pancreatitis'.

Finally, the authors mention that our group would have a lower threshold for surgery and that we may be operating unnecessarily in patients with acute pancreatitis. The fact that C-reactive protein has been shown to be a very valuable parameter in indicating pancreatic necrosis has nothing to do with our indication for surgery which is based on clinical criteria such as multiorgan failure or sepsis[7]. Therefore, as we have described in the past, C-reactive protein is more likely to be of value and to be adopted into routine clinical practice than, for example, multiple factor scoring systems; this acute phase reactant does help in the staging of this disease but certainly it does not provide the indication for surgery.

Authors' reply

Sir
We agree there may be variation in the results from different assays used for the estimation of C-reactive protein but currently there is no evidence that the method we employed (Abbott TDX, Abbott Laboratories Ltd., Wokingham, Berkshire, UK) reports higher values than laser nephelometry (Behring Werke AG, Marburg, FRG) employed by Buchler *et al.*[1] and, if anything, may result in lower values Indeed the overall scatter of C-reactive protein concentrations observed in the two studies appear to be similar. Their cut-off level for C-reactive protein of 100 mg/l for the prediction of 'pancreatic necrosis' remains difficult to explain. Fifty-seven (79 per cent) of our patients would have 'pancreatic necrosis' predicted according to this criterion, but only six came to surgery We have observed high C-reactive protein levels in many patients with mild, uncomplicated pancreatitis (*Figure 5*)[2] and perhaps if they had studied more than 13 of such patients different conclusions regarding the cut-off level may have been reached

With regard to the criteria for surgical intervention, while some of our German colleagues' work makes it clear that clinical, computed tomographic and laboratory criteria are utilized together to aid the decision-making process[3], in other work there is an impression given that serum factors such as C-reactive protein can be employed as specific indicators[1]. It is this latter recommendation which can cause problems

Biliopancreatic bypass in the Prader–Willi syndrome

Sir
We read with interest the paper by J. J. Brossy (*Br J Surg* 1989, **76**. 313). In his case report, the author states that in patients with the Prader–Willi syndrome 'gastric stapling aggravates the emotional issues' and therefore should not be performed.

We would like to present our experience with a 29-year-old man, showing several clinical features of this syndrome[1] The patient was superobese· height 145 cm, weight 160 kg, body mass index 76 kg/m^2 A gastric bypass (Mason–Griffen modification) was performed The postoperative course was uneventful except for minor wound infection. The patient was dismissed from hospital 25 days after surgery. At the last follow-up (7 months after operation), his weight was 126 kg (a weight reduction of 34 kg), and he had no problems with food intake.

Although long-term results are yet to be assessed we think that a gastric bypass may be an effective treatment of morbid obesity in the Prader–Willi syndrome.

Leucine kinetics in surgical patients

Sir

Recently published studies by Harrison *et al.* on leucine kinetics in surgical patients (*Br J Surg* 1989; **76**: 505–8 and 509–11) provide a welcome analysis of the conflicting results of studies of whole-body protein metabolism in the context of elective surgery and malignancy respectively. The first paper seems to be a faultless study and analysis, but the second is marred by the fact that the groups reported are too small for firm conclusions to be drawn, although the data can be analysed by the Mann–Whitney *U* test If groups 2, 3 and 4 are taken together and compared with the controls by the same test, the probability that leucine flux is elevated in patients with malignancy is only $P = 0{\cdot}168$ (values estimated from *Figure 1*, page 510). The small group with benign disease and three low values in the group with malignant disease account for this. Inspection of the results reveal that 12 of the 15 values in the group with malignancy lie above the median value for benign disease and six of these are well above the highest value in the controls.

The question that needs to be addressed is why do some individuals with malignant disease have raised leucine flux or nitrogen turnover? There need be no assumption that any effect of malignancy on protein metabolism is related to tumour burden Such an effect, if there is one, may be mediated by a macrophage factor, tumour necrosis factor or cachectin[1] Here an analogy may be made with the effects of interleukin 1 in trauma and sepsis[2]. The presence of a tumour may be sufficient to switch on such a response which may vary between tumours of differing histological types or even between tumours of a similar type This would explain the spread of results within the groups with malignant disease and the variation of results between studies.

The hypothesis that 'host' immune responses to some tumours are responsible for systemic metabolic changes needs to be explored.

Author's reply

Sir

While we are grateful for Mr H. C. Ward's kind remarks relating to our review of the relevant literature, we find ourselves unable to accept the method he has chosen to criticize our scientific presentation If statistical methods are to serve any purpose it must surely be to encourage the rational and honest examination of the actual data obtained. Asking that the three lowest results are ignored to illustrate a possible trend is as meaningless as suggesting that the three highest results are discounted.

The result of the conventional statistical analysis of our study showed no consistent effect directly attributable to the presence of a colorectal malignant tumour. We would accept that this does not exclude the possibility that there is a subset of patients with such tumours who may have altered nitrogen metabolism. To test such a hypothesis, which we feel should certainly precede any speculation on the pathophysiology involved, would require a different approach, and almost certainly a different methodology, to the one we chose

Operative mortality after perforated peptic ulcer

Sir

Mr A. B. S. Ball and colleagues are to be congratulated for their paper (*Br J Surg* 1989; **76**: 521–2) which will undoubtedly reawaken interest in the conservative management of perforated duodenal ulcer. Several points are worthy of comment.

Risk factors affecting the outcome in perforated ulcer surgery have been previously documented in a prospective manner[1] It is known that conservative management in the 1950s could produce results comparable to those achieved by surgery today[2]. Our recent prospective randomized trial[3] has adequately confirmed this impression as well as demonstrating that a 12-h period of conservative therapy does not compromise outcome irrespective of further management. Furthermore, adequate protocols exist for the better targeting of selective treatment of patients suffering perforated duodenal ulceration utilizing water-soluble contrast studies during this initial 12-h period[4].

Such foreknowledge can only lead to the better selection of patients likely to benefit from surgery and contribute also to the improved non-surgical management of those who would carry an unreasonable surgical risk.

It should be stressed, however, that the elderly represent a group of patients who localize perforations poorly and although surgery should be avoided if at all possible there should be no undue delay if radiological and clinical evidence of improvement is lacking after 12 h of therapy.

Contrast-enhanced CT scan in the early phase of acute pancreatitis

Sir

We have read the recent paper by London *et al* (*Br J Surg* 1989, **76** 268–72) with interest and considerable concern. The authors claim that 'pancreatic size index $\geqslant 10\,\text{cm}^2$' (product of pancreatic head and body measurements) represents the simplest computed tomographic (CT) criteria which is applicable to practice, best correlated to the severity of acute pancreatitis, and the 'unique CT parameter for local complications' This index appears over-simplified as great variations exist amongst normal subjects, for instance, young subjects have a larger pancreas than older ones, pancreatic lipomatosis will yield falsely high values and pancreatic atrophy, which is frequent in old and alcoholic patients, will furnish a falsely reassuring index No reference values of pancreatic sizes are given by the investigators CT scanning was not performed on all patients during the study More than half of the deceased patients were not scanned compared with 86 per cent of those with mild pancreatitis; thus excess benign disease was presented, with only six fatal cases! Most other reports[1–3] have exclusively studied severe pancreatitis. Our study[4], although primarily directed at unselected patients contained a slight predominance of the severe form Furthermore, referring to the definition of the disease for their recruitment of patients (serum amylase concentration >3 times the upper reference value) we stress that a significant number of acute pancreatitis patients were underdiagnosed, particularly those of alcoholic origin We recently found that up to 19 per cent of patients with acute pancreatitis had no significant elevation of serum amylase concentration at admission[5]. Regarding this definition and the large number of patients with mild pancreatitis, we do not consider this an unselected study

Finally, the 72 h delay before obtaining computed tomography is too long as the main advantages of early scanning are early confirmation of the diagnosis and prediction of future complications. In our recent prospective study of 202 patients[4], CT scans were performed within 36 h of admission of which 80 per cent were within 24 h. As a result of our investigations, CT had a diagnostic sensitivity of 92 per cent and specificity of 100 per cent. Extrapancreatic spread

(EPS) was found to be of paramount importance in establishing early prognosis and, in this setting, appeared to be of complementary value to clinicobiochemical criteria The type and extension of the oedema correlated to the severity of the disease, and particularly to local complications. In the absence of phlegmonous EPS (i.e. even with the oedematous EPS) the clinical course was mild with no fatalities, whereas in its presence the mortality rate increased to 28 per cent, and exceeded 40 per cent when the phlegmon extended to three or more extrapancreatic areas Arguing the complexity of such grading, London *et al.* have simplified all extrapancreatic manifestations of acute pancreatitis to the 'loss of peripancreatic tissue planes' and, although this later CT criterion had a significant value on the prediction of overall complications ($P = 0\,006$) and was almost significant in predicting local complications ($P = 0\,06$), the authors do not further develop the subject We are also puzzled by the statement that 'contrast-enhanced CT scan adds nothing to a plain scan in establishing the prognosis of acute pancreatitis' This should probably be imputed to the technique of enhancement using slow infusion of contrast media, which often does not allow visualization of pancreatic necrosis, or the differentiation between pancreatic parenchyma and peripancreatic spread (leading to spurious pancreatic measurements[1]), or the differentiation between oedematous and phlegmonous EPS Like others[1–2], we found that rapid-bolus intravenous infusion is mandatory for an optimal enhancement Finally, the renouncement of the Hounsfield units for the evaluation of pancreatic and extrapancreatic enhancement is misleading.

However we agree that routine CT scanning in pancreatitis would be unreasonable and we regret that the authors do not propose situations in which it would be suitable In our opinion, CT scanning is indicated· (1) in all cases of doubtful diagnosis (particularly in the case of normoamylasaemia), (2) in patients presenting some degree of severity in terms of clinicobiochemical criteria (i e. three or more criteria) – the absence of phlegmonous EPS should be reassuring while its presence and extension should alert the clinician of future complications, (3) in all prospective studies A CT scan represents to date the diagnostic 'gold standard' and would allow, in combination with clinicobiochemical criteria, more objective early grading of the severity of the disease

Authors' reply

Sir

We are grateful for the interest that Drs Clavien, Hauser, Meyer and Rohner have shown in our paper We did not claim that a pancreatic size index of $\geqslant 10\,\mathrm{cm}^2$ was a 'unique CT parameter for local complications' but state that we found that this was the CT size index which best predicted the overall severity of pancreatitis As we stated in the paper, we felt that any CT criterion used to predict the severity of pancreatitis should be relatively simple so that it could be applicable to general surgical practice We did not provide normal pancreatic size indices because, of course, for any one patient admitted with established acute pancreatitis there is no way of knowing their normal size index and comparing it with the size index of the inflamed pancreas. It is more relevant to know whether the pancreatic size indices of patients with established pancreatitis can help predict those who will go on to get a severe attack As stated by Dr Clavien and his colleagues the majority of reports concerning the prediction of the severity of acute pancreatitis by computed tomography have exclusively studied patients with severe pancreatitis We intended to scan all patients admitted with acute pancreatitis but for logistic reasons managed to scan 83 per cent There were inevitably relatively more deaths amongst the group of patients who were not scanned because seven patients who were moribund on admission were not referred for CT scanning We feel that this in no way weakens the study because these patients already had a clinically obvious severe attack[1] We included in our study patients with a first attack of pancreatitis and with an amylase concentration > 1000 units/l We note that the incidence of alcoholic aetiology in Dr Clavien's study was twice that in our study and, although during the period of our study a small number of patients with alcoholic pancreatitis were admitted with pain and an amylase concentration < 1000 units/l, none of these patients in our experience has gone on to have a severe attack and we therefore felt that it was not necessary to include them The purpose of this study was specifically to assess the value of computed tomography for the prediction of severity, not the diagnosis of acute pancreatitis.

Dr Clavien and colleagues state that in their study computed tomography had a sensitivity of 92 per cent for the diagnosis of acute pancreatitis, which is the same as our recently published figure[1] Surely it is not possible to produce a figure for the specificity of computed tomography for the diagnosis of acute pancreatitis unless all patients with abdominal pain admitted to an institution have a CT scan? Like Dr Clavien we found that there were highly significant differences in the CT appearances of patients who went on to get mild or severe attacks but we felt that the sensitivity and specificity of these criteria were not good enough to recommend the use of computed tomography in routine clinical practice Dr Clavien does not state the sensitivity or specificity of his various CT criteria for the prediction of severity. It is clearly stated in our paper that our technique for contrast infusion is not comparable with that of Block *et al.*[2] or Kivisaari *et al*[3] who used a rapid-bolus infusion technique in patients with established severe disease to detect pancreatic necrosis.

We did not propose situations in which CT scanning would be suitable because we feel that this needs to be investigated by prospective studies We do not agree that computed tomography represents the diagnostic 'gold-standard' because we have found that 6 per cent of patients with clinically undoubted pancreatitis have normal CT appearances Thus whilst an abnormal CT appearance confirms the diagnosis of acute pancreatitis a normal appearance does not exclude it Whether patients can be selected by biochemical criteria for CT scanning and whether the demonstration of pancreatic necrosis or extra pancreatic spread at an early stage will alter the morbidity or mortality of the disease remain to be determined

Book reviews

The Foot

B Helal and D. Wilson 80 × 100 mm Pp 1279. Illustrated. 1988 Edinburgh Churchill Livingstone. £150 00

The Foot comes as a pair of heavy volumes with two orthopaedic editors and 62 chapters of expert opinion to show that this surgical Cinderella deserves at least equality with the hand. There is, as one would expect, weighty evidence for the anatomical nicety and functional subtlety of this lowly appendage but also much clinically based material There are excellent reference chapters on weighty subjects such as the mechanics, radiology and surgery, but also useful lighter contributions including mythology, chiropody and the risks of dancing Some chapters are refreshingly analytical There is, for example, a comprehensive review of the controversy between conservative and surgical management in the treatment of rupture of the Achilles' tendon The extremely useful K9, with which at least two surgeons have continued to operate despite being in plaster themselves for this condition, is not included but the review concludes that out of the many trials and reports which have addressed the issue, 'persons who benefit most from operative treatment are high performance athletes' Unhappily, there are also many areas of treatment in which even that degree of certainty is lacking and in some chapters we find authors drawing a variable thickness of literary camouflage over their empirical recommendations.

With admirable logic the work begins with mythology and builds through embryology, anatomy, mechanics and pathology to the climax of treatment Mythology is mentioned again, later, not only in obvious form (half a page on the mythology of the sesamoids in a chapter all their own), but also disguised as expert opinion. The foundation subjects of embryology and anatomy lead on to the complexities of gait, pedobarography and electrodiagnosis, and it is quickly apparent that special investigations are of great value in giving clinical judgement some objective help but that the application of these tests to ordinary practice remains limited. We are a long way from being able to place the foot in a machine and tell its future Forty-five pages are devoted to radiography and radiology and the illustrations of correct positioning and results are detailed and clear A description of local congenital disorders and a lucid and mature appraisal of surgery for myelomeningocele then follow. Those who remember the enthusiasm in the 1960s for early closure of the 'open back lesion' and the suffering of many of the survivors detailed by Lorber in 1971 will welcome this sympathetic but positive account; uncamouflaged empiricism is shown here in the grey but enduring light of reappraisal and the Hunterian surgical experiment bears humane fruit. In the treatment of other neurological disorders conservative neurologists would surely not agree that surgery is wise, for example in peroneal muscular atrophy (Charcot–Marie–Tooth) where relapse is admitted to be 'inevitable', nor in Friedreich's ataxia where it is the ataxia which is disabling and not the neuropathy For many uncommon treatments objective reappraisal is awaited.

If the foot is a Cinderella, what is the status of the great toe? Certainly it now has a worthy champion in Derek Wilson who has contributed 72 pages and 241 references to improve our understanding of hallux valgus and rigidus. Many procedures are listed, suggesting that we are still reaching towards the best. The second volume takes us through tropical diseases in textbook form· brief, clear and informative. Ainhum is described separately, declining to give up its mystery in six pages and also enjoying a second appearance as a skin disorder later on The chapter on diabetes gives firm recommendations for management using the author's flow diagrams and is unashamedly empirical recognizing that the basic metabolic derangement remains obscure The references here give historical perspective but there is no modern discussion on the effect of insulin as opposed to oral hypoglycaemic agents on prognosis and the critical importance of recognizing non-clostridial gas gangrene is understated. The description of vascular assessment is slight and few vascular radiologists or surgeons would now even consider transbrachial arteriography. The role of digital subtraction angiography, although described here as a 'useful tool', has yet to be proved as a better investment than a modern conventional examination with non-ionic media, and neither technique can reliably distinguish embolism from thrombosis as the author implies.

The syndrome of Sudeck's atrophy, reflex sympathetic dystrophy or, to give it Dr Glick's preferred term, Algodystrophy, is mentioned not only in his helpful chapter but also appears in the earlier review of systemic disease by Dr Barnes. This is not the only example of avoidable duplication in the work but is an important one since Dr Barnes covers vascular disease in only one page, and space is required in a work of this authority for a vascular specialist

The editors have been ambitious and in a first edition some overlap in subject matter and variation in terminology is understandable, but for the second edition, which is surely deserved, judicious pruning would permit essential new growth. Updating will also be required, for example to bring the recommendations for support stockings into line with recently approved standards, and to expunge some of the traditional but erroneous views about chemical desloughing, topical antibiotics, penetrating gravitational ulcers and sympathectomy for Raynaud's disease.

Cinderella may now go to the ball confident that if she injures her foot, experts from Messrs Helal and Wilson's book will be on hand to explain how it happened and to restore it to fit the glass slipper she deserves. Meanwhile, the vascular surgeons are still in the kitchen waiting for their invitation from these fairy godmothers

Operative Ultrasonography. 2nd ed.

B. Sigel. 160 × 240 mm Pp. 231. Illustrated. 1988. New York· Raven Press $86 50.

The publication of the second edition of this book is timely, given the increasing interest being shown in the use of operative ultrasonography. The editor has the stated aim of informing surgeons and radiologists in the use of ultrasonic imaging in the operating room but, despite extensive revision of the first edition, certain key applications of operative ultrasonography are omitted and I was not convinced of its usefulness in some of the areas covered by the book.

The first three chapters give detailed descriptions of the basic principles and general techniques of ultrasonography, although the section on image orientation, outlining experiments using the ultrasound probe in a water tank, could perhaps have been replaced by more detailed description of image orientation with the normal liver, pancreas, kidney, etc

The chapter on the application of operative ultrasonography during liver surgery has been written by two leading exponents of the technique, but this chapter is of little practical benefit to western hepatobiliary surgeons. There is a detailed description on the diagnosis of hepatocellular carcinoma. Detection of associated daughter nodules and tumour thrombi, and a variety of ultrasound-guided hepatic resections are listed. It seems incomprehensible that there is no mention of the use of operative ultrasound in the detection of 'occult' liver metastases in patients undergoing resection of primary gastrointestinal malignancy, and no mention is made of its role in the evaluation and management of hepatic metastases

The chapters on application of operative ultrasonography in biliary and pancreatic surgery are well written, although no mention is made of its use in assessing hilar cholangiocarcinoma. Its usefulness in renal surgery has been diminished with the introduction of lithotripsy but the chapters relating to vascular surgery and neurosurgery were welcome, since its application in these fields seems to be broadening

I suspect that the enthusiastic operative ultrasonographer would buy this book because of the shortage of written material in this field, but both he and the surgeon wishing to learn the technique would be disappointed since the book fails to give sufficient practical information.

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality.

Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

Swann-Morton Limited, Penn Works,
Owlerton Green, Sheffield S6 2BJ, England.

Royal Postgraduate Medical School
(University of London)

Annual Course in Advanced Hepatobiliary and Pancreatic Surgery

6-10th November 1989

This year's principal Guest Lecturer is

Professor Henry A Pitt, Johns Hopkins Hospital, USA

Other guest speakers include:

LH Blumgart *(Bern, Switzerland)*, J Buckels *(Birmingham)*, MJ Cooper *(Exeter)*, J Farndon *(Bristol)*, TF Gorey *(Dublin)*, PA Grace *(Dublin)*, J Hermon-Taylor *(St George's)*, KEF Hobbs *(Royal Free)*, I Ihse *(Sweden)*, CW Imrie *(Glasgow)*, GAD McPherson *(Wycombe)*, GJ Poston *(St Mary's)*, MC Puntis *(Cardiff)*, B Ringe *(Hannover, Germany)*, K Rolles *(Royal Free)*, BJ Rowlands *(Belfast)*, RCG Russell *(The Middlesex Hospital)*, H Saeger *(Mannheim, West Germany)*, R Williams *(King's College)*

and from the Royal Postgraduate Medical School:

RCN Williamson, IS Benjamin, JN Thompson, NA Habib, A Adam, SR Bloom, A Booth, CS Foster, A Kennedy, M Roddie, K Vallis, RB Welbourn

Topics covered include:

Investigation of liver and biliary tract, primary and secondary liver tumours, operative and non-operative management of gallstones, acute and chronic pancreatitis, pancreatic cancer, pancreatic endocrine tumours, biliary strictures, HPB trauma, liver transplant, technical aspects of HPB surgery with film and video presentations and 'How I Do It' sessions

Course Organisers:	Mr IS Benjamin, Professor RCN Williamson
Course Fee (inc. catering):	£325
Information from:	Wolfson Conference Centre Royal Postgraduate Medical School Du Cane Road London W12 0NN
Telephone:	01-740 3117

The British Journal of Surgery

Volume 76 Number 9 September 1989

Controversies in General Surgery

T G Allen-Mersh
with 20 contributors

Arguments for and against 10 controversial issues in general surgery are reviewed in debates between surgeons. The intention is to present the arguments, giving supporting evidence as well as pointing to the flaws on both sides of each argument. Consideration of these controversies will hopefully help the reader to decide what is right for the patient.

- **An easy means for surgeons in training to familiarise themselves with the arguments and the literature background to the major controversies in surgery**

£10 net June 1989 paperback
128 pages ISBN 0 340 49649 5

Day Care

Surgery, Anaesthesia and Management

Edited by Elizabeth G Bradshaw and Harold T Davenport
with 17 contributors

Day care surgery has expanded greatly over the last twenty years. This is the first major reference work on day care covering the whole field from the establishment of a unit to the procedures which are conducted within it.

- **This book is intended to assist in the setting up of a unit, and to assist and encourage those already working in this area**

£25 net June 1989 hardback
208 pages ISBN 0 7131 4560 9

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

Reviews

'What differentiates this textbook of surgery from many others is the clarity and simplicity of the text, the very liberal use of complementary tables, the illuminating simple diagrams, and the book's clinical relevance. The ease with which it may be read and the subject material understood makes this book a superior choice for students and residents interested in learning the essentials of surgical practice.'
The New England Journal of Medicine

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'. . . Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'
New Zealand Medical Journal

Concise Contents: General surgical aspects • Trauma • Head and neck surgery • Neurosurgery • Thoracic surgery • Cardiac surgery • Vascular surgery • General surgery • Genito-urinary surgery

International Medical Seminar

Osteo-arthritis of the knee: aetiology, management and recent advances

10 - 15 December 1989, Stanmore, near London

The purpose of this seminar is to update participants on recent advances in the management of osteo-arthritis of the knee.

The discussion will cover the pathogenesis of osteo-arthritis including traumatic injury and degenerative arthritis; operative and non-operative treatment, including the use of cartilage grafting and carbon fibre resurfacing of the joints and the principles and future of total joint replacement.

A prominent feature of the seminar will be case presentations through video and direct patient contact. There will be opportunity for discussion and selected participants will be invited to give presentations.

The course will be directed by **Professor George Bentley**, University Department of Orthopaedic Surgery, Royal National Orthopaedic Hospital, Stanmore.

The course is designed for orthopaedic surgeons with a particular interest in osteo-arthritis of the knee.

There are vacancies for 35 participants.

Course fee: £505; accommodation charge· £340;
total fee: £845.

Resident participants will be accommodated in single rooms with private shower or bathroom at a hotel. The seminar sessions will take place at the Royal National Orthopaedic Hospital, Stanmore.

AVAILABLE NOW! CURRENT PRACTICE IN SURGERY

The quarterly international review journal which systematically and comprehensively covers all the disciplines of general surgery over a three-year period

Free sample copy available on request

Chairman: A Cuschieri
Executive Editor W E G Thomas
Editorial Committee: K J Burnand, T Cooke, J R Farndon, C Quick

Contents of the first issue:

Acute non-variceal haemorrhage
Variceal haemorrhage
Recurrent obscure gastrointestinal haemorrhage
Endoscopic control of haemorrhage
Management of diabetic patients undergoing surgery
Insertion of vena caval umbrella
Arterial embolism
Soft tissue sarcomas of the extremities
Renal trauma
Fissure-in-ano
Stomach carcinoma following oesophagectomy

plus

Self-Assessment
Lessons from Clinical Practice
Book Reviews
Letters to the Editor

Each paper succinctly summarises the most recent surgical knowledge and practice on each topic.

Qualified and trainee general surgeons at all levels will find **Current Practice in Surgery** an invaluable source of the most up-to-date information currently available

Subscription Information ISSN 0952-0627

Institutional Rate £79.60 (UK)/$179.00 (USA)/£99 00 (Elsewhere)
Individual Rate: £49.50 (UK)/$109.00 (USA)/£62.00 (Elsewhere)

YES! Please send me a free sample copy of the first issue of **Current Practice in Surgery**

BASO 1989 FORUM

CANCER OF THE COLON AND RECTUM FOR THE GENERAL SURGEON

THURSDAY 30th NOVEMBER, 1989
THE ROYAL SURREY COUNTY HOSPITAL, GUILDFORD, SURREY

An in-depth all day course designed for established Consultants and those in training

TOPICS

Epidemiology, Population Screening, Investigations, Pathology, Tumour Markers, Role of Chemotherapy and Radiotherapy, Management of Liver Metastases, Primary and Reconstructive Surgery.

SPEAKERS INCLUDE

S J Arnott
H Ellis, CBE
J D Hardcastle
R J Leicester
C G Marks
R J Nicholls
J M A Northover
G D Oates
R K S Phillips
N A Shepherd
I Taylor
J A H Waterhouse

Registration Fees Including Lunch:

Consultants & Senior Lecturers — £60.00
Delegates below these grades — £35.00

Further details and registration forms from
Mrs S L Hatcher, British Association of Surgical Oncology, Royal College of Surgeons,
35-43, Lincoln's Inn Fields, London WC2 3PN.

Management of ingrowing toenail

Fourteen years ago this journal published my first paper: a review of the management of 200 patients who attended the Western Infirmary, Glasgow, between 1966 and 1970 with a diagnosis of ingrowing toenail[1]. Avulsion of the hallux nail was the most common treatment recorded (72 per cent) with 35 per cent of these patients having more than one avulsion at the same site. General anaesthesia was used for 30 per cent of hallux nail avulsions. Recurrence of ingrowing toenail occurred in 64 per cent of the patients after the first avulsion and 80 per cent after subsequent avulsions. The most common surgical procedure used to treat ingrowing toenail was total proximal nailbed ablation as described by Zadik[2] General anaesthesia was employed for 97 per cent of these procedures and a 16 per cent symptomatic recurrence rate was noted. The paper recommended that local analgesia be used for the vast majority of hallux nail avulsions and nailbed ablation procedures. A management protocol was outlined that advocated nail avulsion at the first hospital presentation; this was backed up with advice to the patient on care of the new hallux nail during regrowth. Nailbed ablation using the Zadik technique was recommended for any postavulsion recurrence of ingrowing toenail. In writing this article I have reassessed my 1975 management protocol for ingrowing toenail and attempted to highlight the changes in management that have occurred over the last 14 years.

Conservative treatment of ingrowing toenail has never been popular with surgeons. This form of management is time consuming, demands a high level of patient co-operation and requires patience from both doctor and patient. There is no doubt, however, that conservative treatment of ingrowing toenail can be successful, especially in young adults with early disease and a non-dystrophic nail. This was well illustrated in 1963 by Lloyd-Davis and Brill[3], who reported that 60 per cent of the patients attending their toe clinic at St. Thomas' Hospital, London, with ingrowing toenail were cured by, or were responding well to, conservative treatment. The article by Reijnen and Goris[4] in this issue supports a role for conservative treatment of ingrowing toenail. The authors report a high initial success rate (96 per cent) for conservative management in young patients with early disease but admit to a lower success rate and higher recurrence rate when managing chronic ingrowing toenail conservatively.

Arguably the most significant advance in the efficiency of surgical management of ingrowing toenail over the last two decades has been the acceptance that the vast majority of patients can be treated using local analgesia rather than general anaesthesia. The ring block technique employing a 50:50 mixture of 2 per cent plain lignocaine and 0·5 per cent bupivacaine gives excellent analgesia starting within a few minutes of injection and lasting for 6–8 h by which time most patients are settled comfortably at home. This technique should be mastered by all trainees in general surgery.

The use of hallux nail avulsion to treat ingrowing toenail has declined significantly over the last 14 years. Most surgeons are unhappy to accept a recurrence rate of over 50 per cent and are aware of the difficulties associated with optimal care of the regrowing nail. Nailbed ablation using phenol has removed the need to avulse the hallux nail to eradicate sepsis before excision ablation of the nailbed, and this advance has further limited the use of hallux nail avulsion. Simple avulsion should now be confined to the urgent situation in an accident and emergency department where severe pain from ingrowing toenail requires treatment in the absence of expertise to carry out a definitive procedure.

Publications over the last 14 years have confirmed that nailbed ablation using phenol as described by Ross in 1969 (Reference 5) is superior to nailbed excision techniques as described by Winograd[6], and Zadik[2]. Phenol cauterization of the nailbed is preferred by patients and is associated with a lower nail regrowth rate than nailbed excision[7–11]. Ramsay and Caldwell[10] report a 3 per cent recurrence rate from 1013 phenol cauterizations followed for 12 months, while Young and Rutherford[12] report a 7 per cent recurrence rate occurring within 1 year in 60 patients followed for 3 years. Technique is important and attention must be paid to details outlined in the literature. Haemostatis is essential during phenolization as

0007–1323/89/090883–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

blood effectively neutralizes phenol cautery. Phenol must be carefully applied because cautery of tissue other than the nailbed increases morbidity and can result in litigation.

Phenolization of the whole proximal nailbed has been commonly used to treat ingrowing toenail. This technique remains appropriate for the management of onychogryphosis and other conditions involving significant nail dystrophia. For true ingrowing toenail, however, it has become apparent that at least the central one-third of the hallux nail should be left and phenolization should be restricted to one or both edges (25–30 per cent on each side) of the nailbed depending on presentation. The splinting effect of the residual nail improves the resultant shape of the hallux. This is more cosmetically acceptable and avoids the risk of hyperkeratosis of the exposed nailbed[10].

For me, the last 14 years have helped to simplify the management of ingrowing toenail. Clinical studies have identified what each procedure has to offer and the options now appear clearly defined. Conservative management may abort some early cases but this form of care calls for interest and expertise[4] and is best delivered at a toe clinic staffed by a chiropodist and a surgeon. Partial phenolization should be offered for established ingrowing toenail and should be carried out by surgeons who have received appropriate training. Patient review after 6 months will provide a useful audit of technical performance.

Selection of patients for breast conservation

That some breast cancers may be safely treated by less than mastectomy is now widely accepted; however, the rules that should govern the choice of patients for this conservative management vary from centre to centre because there is not yet a sufficient body of information on which general principles could confidently be based. Two papers published in this issue of the journal (pages 890–894 and pages 898–900) address the difficult problem of local recurrence after conservative surgery; both show a substantial incidence. In the study from Birmingham the figure was 35 per cent at a mean follow-up of 47 months in a series of mainly elderly patients where surgery had not been followed by radiotherapy. In the series of much younger patients from Nottingham the rate of local recurrence in the breast was 21 per cent. These figures are at the high end of the reported range, the low end of which is in single figures. Zealous conservationists may dismiss these high incidences as due to over-generous selection of patients or flawed surgical or radiotherapeutic technique. By contrast, the diminishing band of unflinching mastectomists may take the figures as confirming their prejudices against any treatment short of mastectomy. The papers should, however, be viewed as stages in the current difficult but crucial process of defining the proper indications for and strategies of conservation.

When all the evidence is taken into account it seems that youth, a large tumour, vascular or lymphatic invasion, extensive surrounding *in situ* disease, regional lymph node involvement, a high grade tumour and negative oestrogen receptor status may all be separately and interactively related to local recurrence after conservative treatment, just as they are after total mastectomy. Local recurrence is on balance commoner after conservation than after mastectomy but arguably is easier to treat. Whether mastectomy after recurrence in the retained breast carries a penalty of a greater risk of mortality than if mastectomy had been the original treatment remains to be shown. Additionally, it is clear that conservation does not necessarily yield a happier woman than does mastectomy. Thus many questions about the application of breast conservation remain to be answered and it is crucial in the mean time that the practice of breast conservation should be attended by the utmost prudence in selection, care in technique and penetrating pathological and clinical review of long-term as well as short-term outcomes.

Personal comment

The English Surgeon Abroad

Every 2 years there is a meeting entitled the International Surgical Week, hosted by the International Society of Surgery, International Association of Endocrine Surgeons and the International College of Digestive Surgeons, with at least 13 other participating societies or associations. It is a meeting that attracts 3000 surgeons from around the world and has a deservedly high reputation for the quality of its papers, panels and symposia. Some years ago the International Society of Surgeons (originally christened the Société International de Chirurgie) decided that English was to be its *lingua franca scientifica*. All papers are now given in English with no simultaneous translation. Why then is it that so few British surgeons attend these meetings and, in particular, why do so few submit papers for presentation? The number of authors submitting papers for the Toronto conference in 1989 is shown in the *Table*. The Japanese lead the table with 202 authors submitting at least one paper, the West Germans have 135, the USA 110, Italy 64 and Canada (the host country) has 50. The UK's 12th place is behind the USSR and Spain and behind such small population countries as Sweden, Switzerland and Greece.

	Number of authors who submitted one or more papers	Number of panel moderators invited by scientific committee	Number of panel members chosen by scientific committee
Japan	202	0	5
FRG	135	0	10
USA	110	4	23
Italy	64	1	7
Canada	50	3	8
France	42	0	8
Sweden	36	2	5
USSR	31	0	0
Spain	30	0	1
Greece	27	0	0
Switzerland	22	1	2
UK	21	5	10
Austria	21	0	0

What are the reasons for such poor British participation? Is it because of poverty, arrogance or apathy? It could be argued that the Swedes are financially subsidized to attend such meetings and that there are at least 64 rich general surgeons in Italy. However, it is unlikely that the average consultant surgeon in the UK is worse off than the average consultant in Spain, Greece or Italy. Arrogance is always a possible motive for the stay-away British; it is possible that they consider that they have such high quality regional and national meetings that there is no need to find out what the rest of the world is doing or thinking However, it is more likely that apathy rather than poverty is the principal reason why they stay away from international meetings. Perhaps it is apathy engendered by too long a training.

Despite the poor British attendance and free paper submission, the rest of the world seems to regard British surgery highly for, of the 16 panel moderators chosen for the Toronto meeting, the largest number (five) come from the UK, one more than from the USA and two more than from Canada. It is possible that the British tend to be chosen to be moderators because of their ability to be understood clearly by most of the rest of the world for whom English is only their second language. Perhaps it is because they mutilate the English language less blatantly than do those from the USA. Surely we must acknowledge that it is only recognized world experts who will be selected as panel participants. It is interesting therefore to consider the distribution of the 79 chosen panelists for the major sessions in Toronto. The UK, with ten, is equal second with West Germany in the league table, not far behind the 23 panelists from the leading nation, the USA.

It is dangerous to draw too many conclusions from these data but it does seem that much of the rest of the world tends to regard highly British surgery or at least some British surgeons. The poor overall submission rate for free papers and poor attendance of British surgeons in general is, I believe, most likely to be related to apathy; possibly the consequence of our over- long period of surgical training. From the time that a British surgeon starts his specialist training, it is between 10 and 16 years before he or she achieves a definitive consultant post. Once a consultant post has been achieved, the appointees are safe and almost 'fire-proof'. Are they also worn out and apathetic as a result of over-training? It will be interesting to see whether the promised alteration in the promotion structure in British surgery makes any difference to British participation in international meetings.

British surgeons have always had a tendency to think of themselves as of the elite; it comes of something of a surprise to me to find that other nations still show a tendency to rate the best British surgeons quite highly.

Typhoid perforation

E. J. Gibney

Beaumont Hospital, Dublin 9, Ireland
Correspondence to: Mr E. J. Gibney

Typhoid perforation of the bowel carries a high risk of mortality and is a common surgical problem in many developing countries. This review examines the pathogenesis, and discusses diagnosis and management.

Keywords: Typhoid perforation, diagnosis, management

Perforation of the bowel is the most serious complication of typhoid fever, and remains a significant surgical problem in many parts of the world[1–5]. It is traditionally associated with a high mortality, not least because it occurs most commonly in areas where optimal medical care is not readily available

It is now generally accepted that the best definitive treatment is surgical[1–3,6,7], and few would now advocate conservative management[8,9]. However, there is no general agreement about the best surgical procedure, and many have been recommended[2,5,6,10,11]. This has often led to less emphasis being placed on the other essential therapeutic measures; aggressive fluid and electrolyte therapy, blood transfusion and antibiotics will all help to reduce mortality[3,7,12].

Pathology

Typhoid fever is caused by *Salmonella typhi*, a Gram-negative bacillus, and is acquired by ingestion of contaminated water or food. The disease has a seasonal incidence, peaking at times of heavy rainfall, when water contamination is more likely[7]. The organism passes through Peyer's patches without causing inflammation. Multiplication occurs in the reticuloendothelial system during an incubation period of 10–14 days. Seeding into the bloodstream corresponds to clinical onset, and during the second week of symptomatic illness the bacteria reach the gut, either via the bile or by bacteraemic spread, and localize in Peyer's patches. Ulceration occurs and there is an associated mesenteric adenitis The main inflammatory cells involved in this phase are macrophages; some lymphocytes are also present, but polymorphonuclear leucocytes are almost completely absent[13]. It has been postulated that much of the damage done may be due to the body's response to the organism (the mononuclear cell response is characteristic of delayed hypersensitivity). This may help to explain the fact that perforation is known to occur also in patients already on anti-*Salmonella* treatment[7].

Macroscopically, Peyer's patches will be seen to be swollen, red and raised, and solitary lymphoid follicles are also affected The mesenteric nodes are enlarged The terminal ileum and caecum are involved, and the appendix may be inflamed. Ulceration with haemorrhage may occur, as may perforation. The ulceration occurs in the long axis of the bowel, and where perforation does not occur and the disease subsides healing occurs without scarring, so that late strictures are not seen. Perforation occurs classically on the antimesenteric border of the terminal ileum[10,12]. Caecal perforation can also occur but is far less common. In about 20 per cent of cases multiple perforations are present[1,7]. The size of the perforation varies, but true microperforations are uncommon and the average diameter[10] is 5 mm. Although this complication may occur earlier[7], it usually occurs in the second week of clinical illness, the average length of the history being 8–11 days[1,10].

The incidence of bowel perforation in typhoid fever varies markedly from place to place and also appears to be changing with time[3,10,14], the highest quoted incidence being from Ghana (17·9 per cent)[7]. Typhoid perforation is commoner in men and in those under 40 years of age[2,4,7].

Diagnosis

Typhoid fever is characterized by fever (which ranges from 38·5 to 40°C), splenomegaly (by the end of the first week) and the appearance of Rose spots (which are difficult to see in deeply pigmented peoples). Rose spots occur in less than 50 per cent of cases, typically on the upper abdomen, and fade in hours or days. Other features include headache, respiratory complaints and relative bradycardia. Constipation may be the predominant feature in a significant proportion of cases, and diarrhoea is not uncommon, especially in children. Abdominal pain may also be a feature, and mental confusion is not unusual Complications include pneumonia, gastrointestinal bleeding, perforation, cholecystitis, cystitis and osteomyelitis. The white blood count is normal or low, with neutropenia. Anaemia is common and often multifactorial. Definitive diagnosis is made by culture of the organism from the blood (weeks 1 and 2), urine or faeces (from the second week on). A rising titre of agglutinin (the Widal test) is usually diagnostic (towards the end of the second week), but a single test may mislead, especially if the patient has had previous TAB vaccination. The differential diagnosis includes malaria, respiratory and urinary infections, viral fevers, meningitis, occult abscess and endocarditis.

The diagnosis of perforation is suggested by increasing abdominal pain, often beginning in the right iliac fossa or lower abdomen and spreading from there. The most helpful clinical signs are tenderness, rigidity, guarding and loss of liver dullness[3]. Free subdiaphragmatic gas is present in up to 75 per cent of cases[7]. The white cell count is not helpful, as it may be normal, low or high[1,3]. The differential diagnosis at this stage includes perforated peptic ulcer and perforated appendicitis, as well as late intestinal obstruction and other causes of ileus, but the preceding history of fever (usually for more than 1 week) and other clinical features of typhoid will usually point to the correct diagnosis. The necessity for prompt surgery precludes confirming the diagnosis of typhoid preoperatively by cultures or by Widal's test.

It is well to remember that the classical signs of perforation may be absent in those who are very toxic, and repeated abdominal examination is stressed by several authors[7,10]. Most clinical difficulty arises in patients known or considered to have typhoid who have abdominal symptoms but equivocal signs and no free subdiaphragmatic gas on X-ray If doubt persists despite repeated clinical examination, exploration is better than continued observation

Management of typhoid perforation

General management

A full blood count, sickle cell test, urea and electrolyte measurement, and urinalysis should be performed, and a nasogastric tube passed. Dehydration is common In addition

0007-1323/89/090887-03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

to having peritonitis, most of these patients have been ill and febrile for a week or more. Fluid and electrolyte replacement should be aggressive, based on clinical findings (blood pressure, pulse rate, degree of clinical dehydration), laboratory findings and response to treatment (urine output should be at least 30–40 ml/h). Correction of blood gas abnormalities and central venous pressure monitoring may be useful in severe cases but are not always possible. Anaemia is common[3,7] and may be partially masked by dehydration. Transfusion is often indicated, but is seldom a top priority in resuscitation.

Many drugs are effective against *S. typhi*, and effective agents include chloramphenicol, amoxycillin, ampicillin, co-trimoxazole and trimethoprim[14]. Chloramphenicol remains the drug of first choice, and is given in an initial dose of 500 mg 4-hourly intravenously in adults (or 50 mg/kg per day). Drug resistance has been encountered and, particularly in epidemics, every effort should be made to establish the drug sensitivity of the organism as soon as possible. If doubt exists a combination of chloramphenicol and amoxycillin or ampicillin is recommended. In perforation, the regimen must include drugs effective against the common enteric organisms, including anaerobes. In practice a combination of chloramphenicol, ampicillin and metronidazole is often used.

Most patients will be resuscitated sufficiently within a few hours to withstand surgery, but a few, usually those with long-standing perforation or those with coexisting disease, will be so severely ill that it may be felt that they are not fit for anaesthesia. Here the clinician must make the final decision, with the reminder that surgery does offer the best hope for survival.

Surgical management

Most authors recommend surgery[1–3,6,7], and few advocates of conservative management remain[8,9]. Many series of patients managed conservatively show mortality rates of over 60 per cent[2,3]. Some authors have pointed out that from time to time the diagnosis will be wrong, but that a perforated peptic ulcer or perforated appendix may be found, and that this is an additional reason for advocating surgery[7,12].

Exploration is usually carried out through a right paramedian incision. An alternative in children is the McBurney or gridiron incision. The risks of subsequent wound dehiscence are greatly reduced, but access for thorough peritoneal toilet is less good and there are theoretical objections to using a gridiron incision in cases where the appendix is left *in situ*.

A thorough laparotomy is carried out, with particular attention being paid to the possibility of multiple perforations, and to excluding areas of localized pus in long-standing cases.

The exact surgical management of the perforation remains controversial, and the following methods are some that have found favour: simple closure[3,6,7,10,12], ulcer excision and closure[15], wedge excision and closure[1], ileal resection and anastomosis, resection and ileotransverse colostomy[2], and right hemicolectomy. In solitary perforations, simple closure with or without ulcer excision remains unchallenged as the procedure of choice[15,16]. Closure should be in two layers, an inner layer of chromic catgut and an outer layer of silk, with the hole being closed in a transverse direction to avoid narrowing the bowel. Multiple perforations pose greater problems, and bowel resection is probably advisable if three or more perforations are present[5]. Right hemicolectomy is only justified in cases of caecal perforation. Regardless of other treatments, any areas of apparent impending perforation should also be oversewn[2,15].

Thorough peritoneal lavage is then carried out with copious amounts of warmed normal saline. Although classically one or more drains have been used in these patients, present knowledge suggests that these may be safely dispensed with. The skin is left open to reduce the incidence and severity of wound infection, and consideration should be given to the use of two or three tension-relieving sutures to minimize the risk of wound dehiscence.

The incidence of postoperative complications is high. Respiratory infections, anaemia and wound infection are all common, and management is often made more difficult by the development of toxic confusional states[2,7,11]. Reperforation or new perforation is possible, and if the diagnosis is suspected against a background of a very ill patient recovering from generalized peritonitis, perhaps with established paralytic ileus, then reoperation is indicated. The mortality rate is high but death is not inevitable. Other major complications include faecal fistula, wound dehiscence and intra-abdominal abscess.

Mortality

The mortality rates from typhoid perforation vary widely in reported series, the range being about 10–60 per cent. Excluding those managed medically, a variety of factors are known to be associated with a higher mortality rate, including late presentation[3,7], female sex[5,7], age over 40 years[7,17], and presence of multiple perforations[5].

Typhoid perforation is now mainly a disease of the developing world, and the medical facilities available for the management of these patients are often less than ideal. It is not surprising that mortality rates vary so widely from place to place. The importance of making the patient fit for surgery cannot be over-emphasized, and in one study[15] an average of 10 h was spent in preoperative resuscitation.

Aftercare

Antityphoid treatment should be continued for at least 14 days If relapse occurs it usually responds promptly to the standard drugs. Instruction with regard to personal hygiene and disposal of faeces and urine is important, as some patients can continue to excrete the organisms for many months afterwards

Long-term complications of surgery include adhesions and obstruction, and incisional hernia. In the few patients in whom terminal ileal resection has been carried out, vitamin B_{12} supplements are necessary.

Conclusion

Ultimately the problem is one that should be solved by public health measures such as the provision of a clean water supply, safe disposal of sewage and instruction in personal hygiene The fact that the organism depends for its continued survival on human-to-human contact makes control measures, if properly applied, more likely to be effective. Prevention by vaccination is incomplete, and impractical in areas where the disease is endemic, but will be useful in localized epidemics.

Meanwhile much can be done to lower to a minimum the risk of mortality in patients with established perforation. Early patient presentation is important, and aggressive initial management with intravenous fluids, antibiotics, blood transfusion and prompt surgery, with careful closure of the perforation, should result in fewer deaths from this dangerous condition

Between November 1979 and December 1986, 263 patients were treated for primary breast cancer by local excision and radiotherapy at the City Hospital, Nottingham. Local recurrence within the treated breast occurred in 56 patients (21 per cent), in 18 (6·8 per cent) of whom it was gross and uncontrollable. An analysis of clinicopathological features shows patient age, nodal status, tumour size, presence of definitive vascular invasion, adjacent ductal carcinoma in situ *and grade to be predictive of local recurrence. A Cox's multivariate analysis of these factors shows the first four to be independently significant. The factors can be combined as a prognostic index which allows identification of patients at high risk of local recurrence. On the basis of these findings we have altered our selection policy for patients suitable for breast conservation.*

Keywords: Breast cancer, breast conservation, radiotherapy, recurrence

Breast conservation treatment by local excision and radiotherapy is increasingly used for primary breast cancer. In Nottingham this treatment has been practised for 9 years. A significant proportion of patients have suffered local recurrence, which we have defined as recurrence in the skin or parenchyma of the treated breast. A number of these have been extensive and uncontrollable. The purpose of this study was to evaluate the extent of this problem, to determine which clinicopathological factors predisposed patients to local recurrence and, based on this knowledge, to redefine our selection policy for primary excision and radiotherapy for breast cancer.

Patients and methods

Primary excision with radiotherapy has been a treatment option offered to patients with breast cancer in Nottingham since 1979. Patient choice has always been an important consideration in planning treatment. Patients with operable breast cancers are counselled by a trained counselling sister and offered a choice between simple and subcutaneous mastectomy or excision and radiotherapy. For the latter treatment the initial criteria were that the tumour should be ≤5·0 cm diameter clinically, should not involve the skin or nipple and should not be deeply fixed.

The operative technique was to obtain macroscopic tumour excision. All patients underwent double node biopsy for prognostic purposes[1] at, or shortly after, the time of tumour excision: one node was sampled from low in the axilla and one from the internal mammary chain via the second interspace.

After surgery patients received whole breast irradiation of 45 Gy and a 15 Gy booster to the tumour bed using a 4 or 6 Mv linear accelerator, over 6 weeks. Build up was not routinely used

A strict follow-up protocol was observed for all patients with 3-monthly review for 24 months, 6-monthly review to 5 years and thereafter annual follow-up. Patients received treated-breast mammography 6-monthly for 2 years and then annually. Only patients likely to have a good prognosis had annual opposite breast mammography.

Age, tumour size and nodal status were recorded prospectively in all patients Tumour size was measured by taking the maximum dimension in the fresh bisected specimen The histopathological grade (based on Elston's modification of the Bloom and Richardson method[2]) was assessed in 253 patients, the remaining ten had ductal carcinoma *in situ* without evidence of invasion and were not graded. Completeness of surgical excision was determined by the proximity of the tumour to the surgically cut edge of the specimen. Initially in the series this was not routinely recorded but latterly it has been recorded as complete, close or incomplete Some other factors have been assessed retrospectively by one pathologist (I.O.E): vascular invasion was defined as the presence of tumour cells in lymphatic or venous spaces within or adjacent to the primary tumour and was scored as present, suspicious or absent, the presence of ductal carcinoma *in situ* adjacent to the invasive tumour was assessed by dividing the microscopic field into four quadrants, determining the presence of carcinoma in each quadrant and scoring the adjacent ductal carcinoma *in situ* on a scale from 0 to 4. The ten patients with ductal carcinoma *in situ* and no invasive tumour were all scored 4. These patients were included as three suffered local recurrence, one with invasive carcinoma.

The contribution of these factors to subsequent local recurrence has been investigated by means of Mantel's life table method A Cox's mutivariate analysis was used to determine which, if any, factors measured were independent predictors of local recurrence within the breast

Results

Between November 1979 and December 1986, 263 patients underwent excision and radiotherapy for primary breast cancer at the City Hospital, Nottingham. The median age of the group was 42 years (range 23–69 years, 95 per cent confidence limits 41 to 43 years). The results were analysed in January 1988 giving a minimum follow-up of 12 months.

Fifty-six patients (21 per cent) have suffered local recurrence in the treated breast. Previously it has been reported from this unit[3] that 68 of 405 patients (16·8 per cent) developed flap recurrence after simple mastectomy and a similar duration of follow-up. The types of local recurrence are seen in *Table 1*. In five patients the recurrence was in the form of a skin nodule and was dealt with by further local excision. In eight of the 35 patients whose recurrence was manifest as a breast lump the tumour developed into uncontrollable local disease despite mastectomy. A further ten patients presented with the treated breast parenchyma (and/or skin) diffusely involved with recurrent tumour; these patients had uncontrollable local disease.

Table 1 *Local recurrence in the treated breast*

Presenting type of recurrence	Number
Skin nodule	5
Breast lump	35
Field change	10

Number at risk									
□	174	161	112	82	62	31	20	9
■	89	71	49	35	26	14	13	7

Figure 2 *Tumour size* versus *local recurrence.* □, *tumour size* $\leq 2\ 0$ *cm;* ■, *tumour size* $>2{\cdot}0$ *cm,* $\chi^2=17{\cdot}1(1\ d.f.)$, $P<0{\cdot}001$ *The number of patients at risk during each time period is given*

Thus, 18 patients (6·8 per cent) have suffered uncontrollable local disease. Of these 18 patients, 15 developed distant metastases, six before or at the time of diagnosis of local recurrence and nine developed them between 1 and 11 months after local recurrence.

Fifty-nine patients developed ipsilateral nodal recurrence; 27 of these also had local recurrence. Thus 32 patients had ipsilateral nodal recurrence alone. Combining breast and nodal recurrence gives an overall rate of 88 out of 263 (33 per cent). The clinical status of the patients at diagnosis of local recurrence is detailed in *Table 2*.

In 36 patients local recurrence was at the same site as the original tumour, in ten recurrence was elsewhere in the breast and ten had diffuse breast involvement.

The influence of the recorded variables on subsequent local recurrence is seen in *Figures 1–7*. Except for completeness of surgical excision, all variables reach statistical significance. The results of the Cox multivariate analysis are shown in *Table 3*. A z value $\geq 1{\cdot}96$ indicates the variable has independent significance. The B value indicates the relative power of each of these variables. As can be seen from *Table 3* four factors have emerged as significant independent variables namely vascular invasion, tumour size, patient age and lymph node stage. Using the B values a prognostic index has been constructed, in the same way that this unit has previously developed a prognostic index for primary breast cancer[4]. Index = (0·7 × vascular invasion) + (0·4 × stage) + (0·25 × tumour size) − (0·06 × patient age).

This index has been calculated for each patient in the study. The indices of the four quartile groups are: 1 = −2·5 to −1·04; 2 = −1·0 to −0·51; 3 = −0·5 to 0·33; and 4 = >0·33.

Using these four groups, life-table analysis of the probability of local recurrence within each has been determined and is shown in *Figure 8*. The 65 patients in prognostic group 4 had a 55 per cent risk of local recurrence at 8 years; the 66 patients in group 1 had an 11 per cent risk of local recurrence at 8 years.

To simplify matters further and give a more usable index we have also constructed actuarial curves for local recurrence

in the two groups of patients with indices lying either side of 0 (*Figure 9*). In patients with high indices the risk of local recurrence by 5 years was 50 per cent compared with 20 per cent in patients with low indices.

Discussion

The rationale for breast conservation therapy is based on retrospective[5,6] and prospective[7–9] studies comparing this therapy with more radical treatment and showing no survival advantage for the latter. Increasingly, breast conservation is being offered to women with breast cancer. Opponents[10] argue that patients treated with less than mastectomy suffer unacceptably high recurrence rates within the treated breast. The published results, however, show great variation in local recurrence rates. Acceptably low rates of local recurrence have been reported by Bartelink and colleagues[11] (2 per cent at 6 years; 585 patients) and Sarrazin *et al.*[12] (5 per cent at 5 years; 592 patients). Higher rates have been shown by Bader and colleagues[13] (21 per cent at 5 years; 112 patients) and Harris *et al.*[14] (22 per cent at 15 years; 152 patients). Such varying results may have several explanations. Certainly patient selection is important and those studies, for example, that only included patients with small tumours (<2 cm) have the lowest recurrence rates. In addition, some studies do not include local recurrences occurring subsequent to or at the time of regional recurrence or distant relapse. This is apparent in some reports. Bartelink and colleagues[11] make the point that six patients were excluded from their analysis because they had clinical symptoms of distant metastases at the time of, or before discovery of, a local recurrence. Other reports may be less forthright. Our rate of local relapse appears high but does include all relapses irrespective of other regional or distant metastatic events. We have also included in our analysis breast relapses at a site different from the original tumour which could represent second primary tumours. In any event, these represent a failure of local treatment.

A major influence on local recurrence rate is the length of follow-up. Kurtz and colleagues[15] investigated the fate of 300 clinical stage 1 and 2 breast cancer patients treated with breast conservation. Ipsilateral breast recurrences continued to occur at 1 per cent per annum after the first decade of follow-up. Our patients have been followed for up to 8 years which is longer than several other series.

It appears that excision of a breast cancer without postoperative radiotherapy leads to a significantly higher rate of early local recurrence than after excision followed by radiotherapy[16]. The dosage may also be important and some institutions give higher doses than others. Although, as a result, the rate of local recurrence may be decreased, this may be to the detriment of good cosmesis. In our patients there were no poor cosmetic results and we certainly have not encountered the shrivelled fibrotic breast sometimes seen after radical radiotherapy, nor telangiectasia in the skin of the treated breast.

A number of studies have addressed which features may predict local relapse. Schnitt and co-workers[17] found that extensive intraductal carcinoma and high grade were important. Bartelink *et al.*[11] and Peterse *et al.*[18] reported an association between extensive ductal carcinoma *in situ* and subsequent local recurrence. One explanation for this is that ductal carcinoma *in situ* may be relatively radioresistant[19]; it is also frequently multifocal[20]. In our series we have confirmed that those patients with extensive adjacent ductal carcinoma *in situ* (4 quadrants) were more likely to suffer local recurrence than those with a less extensive component (0–3 quadrants; *Figure 7*).

In this study patient age, tumour size, histological grade, lymph node involvement, definitive vascular invasion and adjacent ductal carcinoma *in situ* all appear important. Completeness of excision does not appear to be predictive although data are not available on all patients.

We have shown an increased risk of local recurrence in the younger patients, confirming other reports[6,21]. This is clearly a problem as it is generally the younger patients who wish to conserve their breasts. The median age of patients in our study is 42 years and appears lower than in a number of other reports[12,22].

Other than patient age, three factors, i.e. tumour size, presence of vascular invasion and nodal stage, emerge from the Cox analysis as independent predictors of local recurrence. The prognostic index we have developed from the Cox analysis allows us to identify those patients who are at a high risk of local recurrence and who, in our opinion, should undergo mastectomy if unfavourable characteristics emerge from the histological examination of the excised tumour.

It has been claimed[15,23] that subsequent survival is not impaired in patients undergoing mastectomy for local relapse after conservation therapy compared with those suffering local recurrence after mastectomy as the initial treatment In addition, if local relapse can be controlled by subsequent mastectomy it need not present a major cause for concern. It is too soon to make these claims and data are required on the long-term outcome of patients who have undergone mastectomy for local recurrence after breast conservation. Furthermore it has been shown[24] that psychological morbidity is not reduced by breast conservation compared with mastectomy. A woman who suffers local recurrence is likely to suffer anxiety at a level comparable to that encountered when her tumour was first diagnosed There are, therefore, good reasons why attempts should be made to minimize local recurrence. Our main concern, however, is for those patients who have developed uncontrollable local disease; some have undergone extensive surgical resections, omental flaps and skin grafting but despite these measures the tumour has progressed relentlessly on the chest wall. Although 15 of the 18 patients with uncontrollable local recurrence had evidence of widespread disease and thus a dismal prognosis, we would wish to prevent these terminally ill patients having the additional stress of a large fungating tumour mass on the chest wall. In 13 (72 per cent) of these 18 patients with gross uncontrollable local disease the prognostic indices were greater than 0 and using our new criteria they would have been advised against breast conservation.

Many clinicians now advocate breast conserving surgery for primary breast cancer. The popular press has encouraged the belief that breast conservation is the treatment of choice and that mastectomy is an outdated and unnecessarily mutilating procedure. As a result many patients think that mastectomy is never indicated. We should exercise caution and not allow over-enthusiasm for what can be an excellent treatment option to cloud judgement, ultimately to the detriment of the patients. In practical terms our results would suggest that, in most cases, the presence of definite vascular invasion in a tumour should preclude breast conservation. We believe lymph node biopsy is important and will yield useful prognostic information which will help decide whether conversion to mastectomy or adjuvant therapy is indicated. The results of a recent study in 693 patients at this unit would suggest that we can omit the internal mammary node biopsy in patients who have laterally placed breast tumours; but in medial tumours biopsy of this node gives useful prognostic information. We have no intention of altering the dose of radiation given.

Had our index been available and applied to patients at the outset of this series the number eligible for breast-conserving surgery would have been reduced by 33 per cent using a cut-off of 0 (*Table 4*). Total local recurrences would have been reduced by 64 per cent and uncontrollable local recurrence by 72 per cent. A cut-off of +0·5 would not have allowed an adequate reduction in local recurrence and −0·5 would have excluded too many patients from the option of breast conservation

On the basis of our findings we have now altered our selection policy. Patient choice is a policy in our unit but those with tumours greater than 3 cm clinically or with

Table 4 *Predicted numbers of patients suitable for conservation and suffering local recurrence based on prognostic indices*

Index	Cases suitable for conservation	Local recurrence	Uncontrolled local recurrence
Not applied	263	56	18
Cut-off +0·5	213 (81)	33 (59)	9 (50)

Cut-off −0·5	134 (51)	16 (29)	3 (17)

Values in parentheses are percentages

mammographic evidence of extensive or multifocal disease are advised to undergo mastectomy. After operation, patients whose clinicopathological features put them at high risk of local recurrence would be advised to have mastectomy. We now intend to prospectively determine if such a change in policy will reduce the rate of local recurrence.

Thyroid lymphoma

J. H. F. Shaw, A. Holden and M. Sage

University Department of Surgery, Auckland Hospital, Auckland, New Zealand

Correspondence to:
Professor J. H F. Shaw

We have reviewed the local experience of 15 cases of thyroid lymphoma with a view to documenting the epidemiology, presentation, management and prognostic factors governing outcome for this rare condition. All the patients were European despite the fact that 15 per cent of the local population is either Maori or Polynesian. The average age at presentation was 62 years and 13 of the 15 patients were women. The duration of symptoms was short: on average 9 months. Where feasible a definitive resection of the lesion was performed but this could only be performed in six of the 15 cases. The commonest histological type was non-Hodgkin's lymphoma which accounted for 14 of the 15 cases with the large cell variant being the most common (five cases). The mean period of follow-up was 3·3 years: only eight patients were alive and well at that time. The prognostic factors that influenced outcome were: (1) the histology of the lesion – large cell lymphoma carried a bad outlook; (2) whether the lesion could be totally resected or not – five out of six patients undergoing total resection remain alive and well; (3) the presence of pre-existing Hashimoto's thyroiditis was a favourable prognostic factor as only one patient without underlying Hashimoto's disease or positive antithyroid antibodies was alive at the end of the study; (4) male sex may also be an unfavourable prognostic factor as both men in the study died of disease 0·3 and 5 years after diagnosis.

Keywords: Thyroid, lymphoma, thyroiditis

Primary thyroid lymphoma is a rare condition accounting for approximately 2 per cent of lymphomas[1–3]. Controversy continues regarding the exact incidence of this condition as well as what prognostic factors govern outcome and what constitutes optimal management. Difficulties in histological differentiation of malignant lymphomas from small cell anaplastic carcinoma and background thyroiditis no doubt contribute to this[3,4].

Auckland is a good area to review the epidemiology of primary thyroid lymphoma as it has a European population of approximately one million as well as the largest Polynesian and Maori populations in the world. In addition the majority of patients in the area are treated in the Public Health System, thus making records readily available.

We have therefore reviewed the local experience of this condition with particular reference to: (a) the relative incidence in European, Maori and Polynesian populations; (b) the sex and age distribution of patients with this condition; (c) the common histological types of lymphoma presenting as a thyroid mass; (d) the effect of a variety of treatment modalities; (e) prognostic factors that influence outcome.

Patients and methods

A retrospective review was performed from the lymphoma files of the haematology, oncology, endocrinology and pathology departments of Auckland public hospital

Two patients with a previous diagnosis of 'small cell anaplastic carcinoma of the thyroid' had their histology reviewed using immunohistopathological staining. As a result, one patient was reclassified as thyroid lymphoma while the other retained the original diagnosis

Results

A total of 15 patients were found to have primary thyroid lymphoma from a total of 720 lymphoma files. The patients were seen in one of the Auckland Hospitals over the period 1976–88.

Histology was classified using the modified Rappaport classification (1979). Under this classification, 'large cell' lymphomas refer to non-Hodgkin's lymphomas of the diffuse, histiocytic type.

The epidemiology details, presentation, histology, management and outcome are summarized in *Table 1*. All patients had a chest X-ray, and other diagnostic investigations included thyroid scintiscan (nine of 15 patients), thyroid ultrasound (eight of 15), bone marrow aspirate and trephine biopsy (11 of 15), abdominal computed tomographic scan (six of 15) Thirteen patients were tested for thyroid antibodies and of these seven were positive.

Discussion

In general terms our findings help to answer some of the questions raised in the introduction. Firstly, regarding the racial and sex characteristics of thyroid lymphomas, there were no Maori or Polynesians with thyroid lymphoma despite 15 per cent of the population being Maori or Polynesian. The disorder is far more common in women, as previously noted[2,5,6], and both men who developed this disorder were dead of the disease at the time of review. The mean age of onset was 62 years with only two patients aged less than 50 years at presentation, and there was no obvious association between age of onset and outcome.

The single most common histological type was non-Hodgkin's lymphoma, 'large cell' type. This is consistent with other studies[2,3,6]. The next most common types were unclassifiable lymphoma and well differentiated lymphocytic. Non-Hodgkin's lymphoma of the large cell type was associated with a bad outlook: four of the five patients were dead of disease at the time of the study and the other had only been followed for 2 months. Other histological types had a variable prognosis.

Aggressive treatment with multimodality therapy did not appear to have a major impact on outcome. Of the patients who underwent some form of surgical resection coupled with radiotherapy and chemotherapy, three of four patients died. Only six patients had completely resectable tumours but of these five were alive and well with a mean follow-up of

3–4 years. Indeed, two patients undergoing surgery were alive and well at 5 years. Eleven patients received radiotherapy and of these six were dead at the time of the study. Six patients were primarily treated with chemotherapy and of these four were dead. On this basis, it is hard to be sure about which therapeutic modality is most appropriate. The literature appears divided and although some authors suggest biopsy and radiotherapy is sufficient to treat all localized thyroid lymphomas[1,6], many authors note a survival advantage in patients with macroscopic removal of tumour along with radiotherapy[2,5,7]. Irradiating the anterior mediastinum as well as the neck has not clearly been shown to improve survival. For patients with mediastinal extension or systemic disease, combined surgery and radiotherapy appear to offer inferior results to using surgery with adjuvant chemotherapy[8].

Overall, after considering our own data and the data available in the literature, it appears that if total resection is possible the outcome is favourable, while biologically unfavourable tumours are little influenced by multimodality therapy. In addition, as mentioned above, the histological type 'large cell' carries a poor prognosis.

The association between thyroid lymphoma and Hashimoto's disease has been recognized for many years[9,10]. In our study eight patients had definite background Hashimoto's thyroiditis and ten had positive serology for thyroid antibodies. The presence of underlying Hashimoto's disease appeared a favourable prognosis indicator, as only one patient without underlying Hashimoto's disease or positive antibodies was alive at review.

There was no clear correlation between the stage of disease presentation and outcome. Both patients with disease localized to the thyroid gland were alive and well after 2–6 years follow-up but there was no difference in survival amongst patients presenting with localized extrathyroid disease, nodal or systemic disease. Some series have shown a poorer prognosis in patients presenting with nodal or systemic disease[11], while data from others support our findings[12].

We conclude:

1. Thyroid lymphoma is primarily a disease of older women
2. Most patients have a short history and have disease that is localized to the neck but unresectable due to invasion of adjacent vital structures
3. The commonest histological type is non-Hodgkin's lymphoma 'large cell' and this carries a poor prognosis
4. There is a strong association between thyroid lymphoma and Hashimoto's disease and the presence of underlying thyroiditis appears to be a favourable prognostic factor
5. Surgical excision should be performed where possible and in patients requiring adjuvant therapy for residual or recurrent disease the outcome is poor despite multimodality therapy.

Wide local excision as the sole primary treatment in elderly patients with carcinoma of the breast

M. W. R. Reed and J. M. Morrison

Selly Oak Hospital Breast Clinic, Birmingham, UK
Correspondence to:
Mr M. W. R. Reed, County Hospital, Greetwell Road, Lincoln LN2 5QY, UK

Clinically localized carcinoma of the breast in 96 women was treated by wide local excision alone. The locoregional recurrence rate was 35 per cent at a mean follow-up of 47 months. There was no significant effect of recurrence on survival because of the relatively high mortality rate from unrelated conditions in these mainly elderly patients. Recurrence was successfully managed with tamoxifen in the majority of cases, with few patients requiring radiotherapy or further surgery. Recurrence in the breast was associated with significantly less systemic disease and mortality than recurrence in the axilla.

Keywords: Breast cancer, wide local excision

In recent years increasing interest has developed in conservative surgery for early breast cancer. In addition to an improved cosmetic result this form of treatment is associated with less operative morbidity and possibly fewer long-term psychological problems than more radical procedures. Several prospective studies have reported similar survival rates following radical mastectomy, total mastectomy, or partial mastectomy combined with postoperative irradiation[1–3]. Radiotherapy after conservative surgery for breast cancer reduces the local recurrence rate but has not been shown to improve overall survival[3,4]. Recurrence rates following conservative surgery without radiotherapy vary from 6 per cent[5] to 37 per cent[6]. Hermann[7] has recently reported similar locoregional recurrence rates (approximately 11 per cent) after partial, total and radical mastectomy in selected patients in an uncontrolled study. However, it is not clear how many of the patients in the partial mastectomy group underwent radiotherapy. Local recurrence in the breast after conservative surgery is more amenable to treatment and appears to be associated with a more favourable prognosis than recurrence after mastectomy which generally heralds systemic disease[4,7,8].

From the evidence available from many uncontrolled[4,5,9–13] and prospective, controlled[1–3] studies it would appear that a more conservative surgical approach to breast cancer is justifiable and that radiotherapy, which is not without complications[14,15], may be reserved for the treatment of the local recurrences that may result from such management. The aims of this study were first to quantify the local recurrence rate after wide local excision of breast tumours in a group of predominantly elderly women with clinically localized disease, and second to assess the management of locoregional recurrence after this form of treatment.

Patients and methods

Patients were offered wide local excision largely on the basis of advanced age or, in younger patients, where there was reluctance to undergo mastectomy. Evidence of systemic disease was excluded by physical examination, chest radiography and liver function tests. There were no specific limitations on tumour size for treatment by wide local excision nor was the presence of clinically enlarged mobile axillary nodes considered a contraindication to this treatment.

The surgical technique involved either a radial or circumferential incision usually including an elipse of skin over the tumour. The aim was to achieve macroscopic clearance of at least 1 cm of the tumour margins Tumours were bisected in the operating room to ensure adequate macroscopic clearance. Axillary node dissection was not performed even in the presence of palpable mobile axillary nodes The breast tissue was repaired with interrupted absorbable sutures and the skin closed with interrupted silk or subcuticular absorbable suture Drains were not routinely used and patients were generally discharged within 48 h Follow-up was according to a standard protocol which included review 2 weeks postoperatively, every 3 months for 2 years and every 6 months thereafter.

No patients in this study received adjuvant therapy and clinically detected recurrence was initially treated with hormonal therapy, radiotherapy or further surgery with chemotherapy reserved for the treatment of further progression.

Statistical analysis was by χ^2 and Fisher's exact tests.

Results

Between 1969 and 1984, 96 patients with a mean (s.e.m.) age at diagnosis of 76(0·8) years underwent wide local excision (*Table 1*). The tumours were present in the lateral breast in 70 per cent of cases while in 20 per cent they were medial and in 10 per cent central. The mean (s.e.m.) tumour size on clinical examination was 3·7(0·2) cm, with four patients presenting with tumours greater than 5 cm in diameter. Palpable, mobile axillary nodes were present in 13 patients (14 per cent) at presentation. Histological classification of tumours is given in *Table 2*; over 70 per cent were infiltrating ductal carcinoma.

At the time of analysis (January 1988), eight patients had been followed up incompletely. Of the remaining 88 patients,

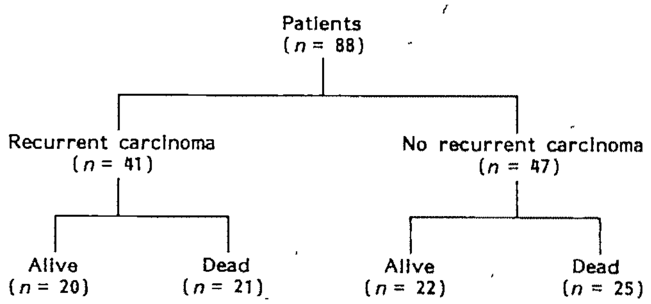

Figure 1 *Outcome in patients with breast cancer treated initially by wide local excision alone*

recurrent cancer had developed at a mean of 31 months in 41 patients (47 per cent), of whom 21 died (*Figure 1*). Of the 47 patients without clinical recurrent cancer, 25 died so that in this group of mainly elderly patients recurrence did not significantly affect survival ($P > 0{\cdot}05$, χ^2 test). Two patients died within 30 days of surgery (one mesenteric infarction and one myocardial infarction).

Locoregional recurrence occurred in 31 cases (35 per cent) at a mean of 31 months (range 3–120 months). Neither the presence of palpable nodes nor tumour size greater than 5 cm significantly increased the risk of locoregional recurrence ($P > 0{\cdot}05$, Fisher's exact test). In 15 patients (17 per cent) isolated ipsilateral breast recurrence occurred; 13 (15 per cent) developed isolated ipsilateral axillary recurrence and three presented with synchronous breast and axillary recurrence. In seven of the patients with axillary recurrence simultaneous systemic disease was present; this is significantly more than in patients with breast recurrence alone where only one patient had synchronous systemic disease ($P < 0{\cdot}01$, Fisher's exact test). The breast recurrences were related to the scar in 13 cases; only two appeared to develop elsewhere in the breast The relationship between tumour size and recurrence is shown in *Table 3*. The risk of breast recurrence tended to increase with increasing size, a trend that was not seen with systemic recurrence.

Tamoxifen was the initial treatment in 20 cases of locoregional recurrence. Tamoxifen proved significantly more effective in the treatment of isolated breast recurrence (response in ten of 11 patients) compared with isolated axillary recurrence (response in two of six patients, $P < 0{\cdot}03$, Fisher's exact test) when assessed by IUCC (International Union for Control of Cancer) criteria. One patient with isolated breast recurrence and two patients with combined breast and axillary recurrence failed to respond to tamoxifen and were subsequently controlled with further surgery[1] and radiotherapy[2].

In the remaining cases, control of locoregional disease was achieved with radiotherapy in eight and further surgical excision in one case. Two patients received no specific treatment for locoregional recurrence associated with advanced systemic disease.

Further progression after initial response was usually treated with radiotherapy, but in some cases further hormonal treatment (aminoglutethimide) or, rarely, chemotherapy was used. Four (22 per cent) of the patients with breast recurrence died of disseminated disease, significantly fewer than those with axillary recurrence, where nine (69 per cent) died of carcinomatosis ($P < 0{\cdot}03$, Fisher's exact test).

Only one patient in this study developed uncontrolled local recurrence. This patient developed axillary and supraclavicular node enlargement 20 months after the excision of a 2-cm infiltrating duct carcinoma. Initial treatment with tamoxifen achieved remission for 19 months after which the nodes reappeared. Radiotherapy again achieved local control for 9 months only to be followed by breast recurrence and further progression despite treatment with successive courses of hormonal (megestrol acetate) and finally chemotherapy. This patient died 6 years after wide local excision with extensive chest wall recurrence.

Discussion

The advanced age of the majority of patients in this study accounts for the high mortality rate in patients without clinical evidence of recurrence and prevents any conclusions on the effect of this form of treatment on survival. However, several large prospective studies have failed to show any survival benefit after radical surgery when compared with more conservative procedures with or without radiotherapy[1–3]. In previous studies, local recurrence has generally been managed by further surgery or radiotherapy. The introduction of tamoxifen has added a new treatment modality for breast cancer, and it is widely used in the treatment of advanced disease[16] and as an adjuvant in the management of early breast cancer[17]. Tamoxifen is also being used as the sole primary treatment in elderly patients. However, only approximately half the patients can be expected to respond, and a recent study comparing tamoxifen and excisional surgery in the management of elderly patients with breast cancer indicates a benefit in favour of surgery[18].

Of the 31 patients with locoregional recurrence, 20 were treated with tamoxifen initially and only seven of these progressed. Tamoxifen proved significantly more effective in the management of tumours recurring in the breast than in those recurring in the axilla. All but two of the remaining patients were treated with radiotherapy or surgery and did not require any subsequent treatment for locoregional recurrence. Only one patient developed uncontrolled local recurrence.

The locoregional recurrence rate of 35 per cent in this series of patients is considerably greater than that seen in studies where adjuvant radiotherapy is used but is similar to the rate seen in other studies where conservative surgery is the sole primary treatment (28 per cent, Fisher *et al.*[3], 37 per cent, Taggert[6]). Such recurrence rates have caused at least one study to be terminated in its early stages[6], despite the lack of convincing evidence that the increase in local recurrence reduces overall survival. The inclusion in the present study of large numbers of patients with T_2 (2–5 cm) tumours contrasts with the majority of previous reports in which only small tumours (< 2 cm) were treated by wide local excision but does not appear to have greatly increased the risk of locoregional recurrence. Furthermore, recurrence within the breast following conservative surgery appears to be more responsive to treatment and to have a more favourable prognosis than skin recurrence after mastectomy which is often associated with systemic disease and short survival[4]

It would appear that conservative surgery alone is an acceptable primary treatment particularly in elderly women who may find it difficult to comply with radiotherapy protocols. Careful follow-up is required to detect the substantial numbers of patients who will develop local recurrence. Local recurrence can usually be adequately managed with tamoxifen alone, enabling radiotherapy and further surgery to be reserved for those who fail to respond. By adopting this policy, more than 50 per cent of the patients in this study managed initially by wide local excision alone have avoided any treatment other than surgery. This approach may also be appropriate in the treatment of selected younger patients with breast cancer, particularly in view of the long-term adverse effects of radiotherapy on survival as demonstrated by Cuzick *et al.*[15] in an overview of radiotherapy trials.

Table 3 *Distribution of tumours by size and site of recurrence*

Non-cyclical mastalgia: an improved classification and treatment

P. R. Maddox, B. J. Harrison, R. E. Mansel and L. E. Hughes

University Department of Surgery, University of Wales College of Medicine, Heath Park, Cardiff CF4 4XN, UK

Correspondence to:
Mr P R Maddox

A prospective study of 72 patients with non-cyclical breast pain was carried out. Non-cyclical breast pain was subdivided into true non-cyclical mastalgia (35 patients) and musculoskeletal pain (37 patients), the latter including Tietze's syndrome and other causes of chest wall pain. Mean age at presentation was significantly greater in the musculoskeletal group (39·3 versus *33·9 years) with a shorter mean duration of pain (14·7* versus *35·4 months) compared with the non-cyclical mastalgia group. True non-cyclical mastalgia was commonly bilateral and located within the upper outer quadrant of the breast, whereas musculoskeletal pain was almost always along the lateral chest wall or costochondral junctions and unilateral in 92 per cent of cases. Breast nodularity was present in 54 per cent of patients with non-cyclical mastalgia, but in only four cases (11 per cent) in the musculoskeletal group. Nine of 14 patients (64 per cent) with non-cyclical mastalgia obtained a good clinical response to drug therapy (over half responding to danazol alone); 19 underwent spontaneous remission, but there was a prolonged mean time to pain resolution of 27 months. In the musculoskeletal group 33 of 34 patients (97 per cent) had a good response to steroid and local anaesthetic injection; three resolved spontaneously without treatment, with a mean time to pain resolution of 17 months. This study indicates that differentiation of musculoskeletal pain from non-cyclical mastalgia may lead to more effective treatment with some prediction of the overall prognosis.*

Keywords: Non-cyclical mastalgia, classification, treatment

Mastalgia is the commonest breast symptom presenting to the general practitioner[1,2]. However, the relative reluctance of patients to seek medical advice[3] coupled with the antipathy towards mastalgia that has prevailed within the medical profession[4–6] has led to little scope for therapy. Some authors have continued to regard mastalgia as a trivial complaint with psychological origins about which they can do little, despite the fact that the widely held view that these women are neurotic has not been substantiated[7].

It was against this background of confusing terminology and ignorance of the aetiology of mastalgia that the Cardiff Mastalgia Clinic was established 15 years ago. The initial work enabled a classification to be developed based on clinical symptoms defining the different patterns of mastalgia[8] and its natural history[9]. Three discrete patterns of breast pain were defined: cyclical mastalgia, non-cyclical mastalgia and Tietze's syndrome. Classification of patients with mastalgia into homogeneous subgroups is obviously a prerequisite of any therapeutic study and subsequently enabled a series of randomized controlled trials to be carried out to assess new treatments of the various groups. There is strong evidence to support a hormonal aetiology in cyclical mastalgia[10,11], which responds well to endocrine manipulation[12,13]. Non-cyclical mastalgia, however, has a lesser response rate to hormonal therapy, and the small improvement over placebo response most probably reflects our lack of understanding of the aetiology of this disorder. This overall poor response may in part be due to inadequate differentiation of chest wall pain from true non-cyclical mastalgia, giving rise to inappropriate treatment in some cases.

When a specialist clinic is set up in a previously neglected field, there is an evolution of diagnostic criteria over the years, leading to an improvement in clinical classification of disease After exclusion of known causes of non-cyclical breast pain a larger group remains, which in our clinic was originally termed the 'periductal mastitis/duct ectasia' group[8]. A further study has led to another term, the 'trigger-spot zone' (along with a 'continuous pain' group) being proposed by Bishop and Blamey in Nottingham[14]. It is therefore clear that there remains a place for further improvement in the classification of non-cyclical mastalgia.

Over recent years in our clinic it has emerged that there is a discrete entity of localized lateral chest wall pain, as well as the medial Tietze's disease, which can be distinguished from non-cyclical breast pain itself by carefully recording the patient's history and by examination With the aim of improving the classification further, we carried out the present prospective study to see if improved differentiation of subgroups of non-cyclical breast pain leads to an improvement in management.

Patients and methods

Initial assessment

Patients with breast disease are first seen in the Cardiff Breast Clinic, which sees approximately 1200 new symptomatic patients per year Breast cancer is excluded by clinical examination, mammography and fine needle aspiration cytology, where indicated. Patients are then reassured of the benign nature of their condition and if the pain continues to be severe (and this is corroborated by a pain chart over 2 months) they are referred to the special mastalgia clinic.

The patients are then subdivided into three main subgroups of breast pain: cyclical mastalgia, non-cyclical mastalgia and musculoskeletal pain, the latter embracing Tietze's disease along with other causes of chest wall pain. Cyclical mastalgia refers to breast pain that occurs predominantly in the premenstruum and is relieved with the onset of a period. Non-cyclical mastalgia is experienced either continuously throughout the month or is intermittent with irregular exacerbations, but the pain and tenderness are always localized to the breast itself. The pain may be diffuse or localized, and when repeatedly localized to the same spot may be termed trigger-spot pain, although we have seen few of these patients.

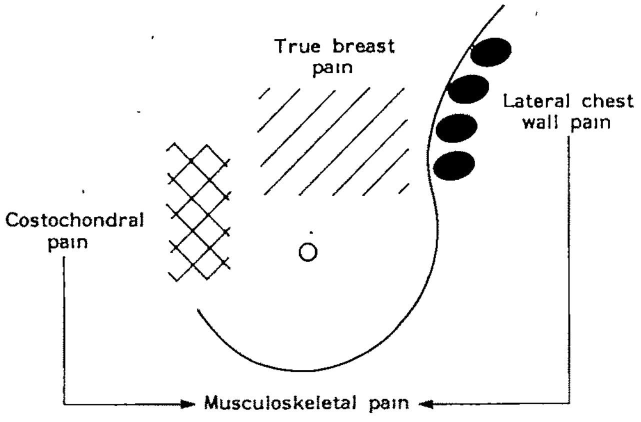

Figure 1 *Site of non-cyclical breast pain*

Chest wall pain may be discretely localized to the costochondral junctions (Tietze's disease) or may be sited more laterally in close apposition to the breast, leading to diagnostic confusion. In these cases careful examination technique will demonstrate that the pain originates from the lateral chest wall region (most commonly found just below the axilla, along the lateral border of the breast on the anterior axillary line), or indeed more medially, deep to the breast itself All these causes of chest wall pain have been grouped together as the musculoskeletal pain group in this study (*Figure 1*).

Examination technique is a crucial factor in the diagnosis of chest wall pain. Tenderness should be localized to a discrete area on the chest wall on examination, and palpation will often reproduce the pain. We have found it helpful to put the patient in the 90° lateral position, with the shoulder fully abducted and the ipsilateral hand behind the head, to aid full examination of the chest wall.

Patients

Over the 4-year period between May 1984 and April 1988, 72 consecutive patients with non-cyclical breast pain were studied prospectively. This group was further divided into 35 patients with non-cyclical mastalgia and 37 with musculoskeletal pain. Patients were regularly reviewed in the mastalgia clinic; initially this was every 1–2 months, increasing to a maximum interval of 3 months throughout the study.

Treatment

Patients with non-cyclical mastalgia were counselled on the various hormonal agents available to treat their condition and then, in accordance with the patient's wishes, offered a course of either danazol (eight), bromocriptine (four), evening primrose oil (six), medroxyprogesterone acetate (one), or simple withdrawal of the contraceptive pill (three); the remainder refused endocrine therapy As expected, multiple courses were required for several women to obtain a response, and those failing to achieve remission were offered analgesia or, as a last resort in one case, surgery.

Patients with musculoskeletal pain were all offered an injection of steroid with local anaesthetic to the exact site of the pain, but three patients declined treatment. This was given as a combined injection of 40 mg methylprednisolone in 1 ml of sterile aqueous suspension with 1 ml of 1 per cent lignocaine to the site at 6-weekly intervals, as necessary, up to a maximum of three injections, with a mean of 1·6 injections required per patient. The injection was always given to the precise spot where pain was localized during examination, usually close to the upper or lower borders of a rib (which also serves as a useful yardstick to assess appropriate depth of the injection) or at the costochondral junctions.

Statistics

The Student's t test was used to compare age at presentation, age at onset and duration of pain for both groups.

Results

Age at presentation

The histogram of the ages at presentation for the two groups of patients, those with true non-cyclical mastalgia and those with musculoskeletal pain, shows a significantly different distribution (*Figure 2*): a mean age of 33·9 years for non-cyclical mastalgia and a somewhat later presentation at 39·3 years for musculoskeletal pain ($P=0{\cdot}025$). The mean age at onset was also earlier with non-cyclical mastalgia (30·6 *versus* 38·4 years, $P=0{\cdot}0016$), but there was a similar range for both subgroups (16–61 years).

Menopausal status was similar in both groups, with the majority of women being premenopausal: 91 per cent of patients with non-cyclical mastalgia, 76 per cent with musculoskeletal pain.

Duration of pain

There was a significantly longer history of symptoms in the non-cyclical group with a mean duration of pain approaching 3 years compared with just over 1 year for musculoskeletal pain ($P=0{\cdot}0013$; *Table 1*).

Site of pain

Musculoskeletal pain was found to be unilateral in over 90 per cent of cases, whereas the non-cyclical group had a mixed spectrum with about half the patients experiencing bilateral pain (*Table 2*). Musculoskeletal pain was found to be along the lateral chest wall or localized to the costochondral junctions in 87 per cent of patients, the remainder being deep to the breast in the upper outer quadrant and other areas of the breast. In the non-cyclical group, however, the site of the pain was isolated to the upper outer quadrant in 80 per cent of patients with the remainder distributed throughout the other three quadrants.

Nature of pain

The character of the pain did not differ overall between the two groups and was usually described as an ache, or less commonly as a soreness, a drawing or a throbbing pain, which was of an intermittent nature in about half the cases in each group. However, radiation of the pain to the axilla or arm occurred in 60 per cent of patients with musculoskeletal pain,

compared with only 49 per cent of those with non-cyclical mastalgia. It was also interesting that breast nodularity was present in 54 per cent of patients with non-cyclical mastalgia, but in only 11 per cent of those with musculoskeletal pain, perhaps reflecting a hormonal factor in some of the non-cyclical mastalgia patients (*Table 2*).

Response to treatment

Nine of 14 patients with non-cyclical mastalgia given drug therapy (64 per cent) had a good clinical response, and over half responded to danazol alone (*Table 3*). In contrast, the vast majority (97 per cent) of patients with musculoskeletal pain responded to local steroid injection. Three patients with musculoskeletal pain refused therapy and subsequently obtained spontaneous relief, with a mean time to pain resolution of 17 months. Spontaneous remission was recorded in 19 of 21 patients with non-cyclical mastalgia who refused hormonal therapy, but the mean time to pain resolution was even more prolonged at 27 months. All therapies given achieved a response within 6 months of commencing treatment, emphasizing the need for improved early diagnosis and treatment of non-cyclical breast pain. Although these treatments were used exclusively in each group, the overall response to treatment was 97 per cent in the musculoskeletal group compared with 69 per cent in the non-cyclical mastalgia group. These two figures of clinical response are somewhat higher than those previously recorded in the overall treatment of non-cyclical breast pain in our clinic[12] and reflect the benefit of improved diagnostic differentiation and therefore specificity of treatment.

Prognosis

There was a higher relapse rate in the musculoskeletal group of around 33 per cent, with a mean time to first relapse of 9·2 months (range 2–32 months). The relapse rate in the non-cyclical mastalgia group was only 11 per cent for those treated successfully with hormonal agents but, as this was only a small group, this difference may prove to be spurious. However, although up to three local steroid injections may have been required, all but one patient in the musculoskeletal pain group achieved remission, whereas five patients (14 per cent) with non-cyclical mastalgia had not obtained remission of their pain at the time of assessment, with a mean follow-up of 9·9 months (*Table 4*).

Discussion

Many women are anxious that breast pain may indicate serious pathology, for example cancer, but the majority respond to simple reassurance when the discomfort is not severe. In a few patients with persistent mastalgia, the pain may be severe enough to interfere significantly with lifestyle, and these patients warrant treatment. Classification of these patients into homogeneous subgroups is an obvious prerequisite to any therapeutic study and this can be achieved in almost all cases referred to our mastalgia clinic.

Although most authors would agree on the criteria for differentiation of cyclical mastalgia and Tietze's disease[8], there does remain some controversy over the subdivision of the non-cyclical group. Bishop and Blamey have described 'trigger zone' and 'continuous breast pain' subgroups[14], which they treated empirically with simple analgesia or surgery (and local steroid injection in a few cases) with some success[15]. They also described two other small subgroups of spinal root syndrome and duct ectasia. It is well described that cervical radiculopathy may mimic breast pain[16], but as cervical spondylosis is not a true cause of breast pain it is better excluded (as indeed it is in our clinic) before a classification of non-cyclical breast pain is carried out The pathogenesis of duct ectasia is still unclear, but this condition may contribute to non-cyclical breast pain

Crile (who earlier referred to non-cyclical breast pain as 'fibrositis') has reported a good response to steroid injection of the breast itself for unilateral localized pain and tenderness[17]. He describes a similar mean age at presentation and response rate to our findings for musculoskeletal pain, which suggests that he may have been treating the same group of patients and achieved a response by virtue of the large volume of fluid injected (10 ml), which would produce a wide diffusion of steroid over the surrounding chest wall. It is interesting that the musculoskeletal pain group presented later with a shorter duration of pain, perhaps reflecting a greater propensity for muscular injury in this age group, although the exact aetiology of this disorder remains uncertain.

Most patients with mastalgia endure an undulating course of relapse and remission with the only prospect of relief being the advent of the menopause[9]. Spontaneous remissions do occur if treatment is not given but, as we have shown, there may be long intervening periods without relief of breast pain causing considerable reduction in the quality of life.

Non-cyclical mastalgia has a lesser response rate to hormone manipulation, compared with cyclical mastalgia, and several

Table 4 *Number of relapses for non-cyclical mastalgia and musculoskeletal pain after treatment or spontaneous remission*

No. of relapses	Non-cyclical mastalgia ($n=35$)	Musculoskeletal pain ($n=37$)
0	28	24
1	2	10
2	0	2
No remission	5	1
Mean follow-up time in months (range)	9·9 (2–30)	14·4 (3–46)

treatments may need to be tried before an optimum response is obtained. In this open study, however, we have shown that the clinical response of the non-cyclical mastalgia group to hormone therapy may be improved using this modified classification, thereby giving rise to a relative increase in the number of patients that may have a hormonal basis for their complaint. Further controlled studies are in progress to examine the efficacy of the injection therapy for musculoskeletal pain and hormonal therapies for non-cyclical mastalgia.

In Japan, R_2 lymph node dissection is standard practice for all curatively resected gastric cancer patients. From 1969 to 1984, data were collected prospectively to evaluate this procedure and to provide information for a more rational approach to node dissection for each individual case. A total of 3843 cases was included in this study and an evaluation was made of the prognostic variables and lymph node involvement at various locations. Using a computer program, it is possible to compile a group of treated patients, with prognostic variables exactly matching those of an individual patient. Analysis of this group can then give an indication of the extent of lymph node dissection required for an individual patient. This paper gives a demonstration of the structure of such a system by means of an example.

Keywords: Computer analysis in diagnosis, preoperative diagnosis, lymph node distribution in gastric cancer, prognosis in gastric cancer

In future, computer analysis will become more and more accessible to physicians and specialists. For surgeons dealing with cancer, the treatment of an individual patient is based on preoperative assessment of prognostic variables, the extent of disease and knowledge of the outcome in earlier comparable cases derived from analysing large groups of patients. It would be valuable if morbidity and mortality data related to a specific individual patient were available.

In Japan, gastric cancer is the main cause of death The Japanese Research Society for Gastric Cancer (JRSGC)[1], advocated that a standard R2 resection should be the minimum procedure in the 1960s[2–5] based on several lymph flow studies (Reference 6 and K Ohta, M. Nishi, T. Nakajima *et al.*, personal communication) which demonstrated the anatomical pathways of metastasis. Although surgeons in Japan are convinced that gastric cancer should be treated primarily as a locoregional disease, the relationship between the primary tumour and the extent of lymph node dissection required remains unclear[7–11]. From 1969 to 1983, data were collected prospectively to evaluate the standard R_2 resection and facilitate rational decision-making regarding lymph node dissection in each individual. Lymph node involvement was evaluated for each location, as were prognostic variables, in 3843 cases entered in this study. In 1984 the computer program was introduced which made it possible to compile a group of treated patients, with prognostic variables exactly matching those of a specific individual patient Analysis of this group is now an important aid in deciding the extent of lymph node dissection required for the patient in question. This paper will show the structure of such a system, in practical terms, by means of an example.

Patients and methods

Data

Data from all patients who underwent resection for gastric cancer at the National Cancer Center, Tokyo, from 1969 up to and including 31 December 1983 were collected prospectively on an agreed protocol outlined by the JRSGC[1]. By the closure date, 3843 cases had been resected curatively or palliatively and were eligible for analysis. The success rate of the operations was evaluated according to the general rules of the JRSGC[1]

Double contrast X-rays were taken preoperatively to estimate the size of the primary tumour and extent of invasion Subsequently gastroscopy was performed and biopsies were taken for preoperative histological confirmation From 1984, endoscopic ultrasound was performed if the results were inconclusive Preoperative examination for the presence of metastases included rectal and gynaecological examination, chest X-rays, ultrasonography and, if required, computed tomography and bone scintigraphy. If patients had a solitary liver or peritoneal metastasis, curative resection was still considered possible[8] Patients with multiple or extensive metastases underwent palliative surgery and were excluded from the study

The seven preoperative variables considered to be important prognostic factors were registered, namely, sex, age, tumour type, depth of invasion, location, diameter of the primary tumour and histological type. Early (I, IIa, b or c, III)[1] and advanced (Borrmann I, II, III, IV)[13] gastric cancers could be classified accurately The following tumour location categories were used upper, middle or lower third of the stomach, and greater curvature, lesser curvature, anterior or posterior wall.

All patients underwent R_2 lymph node dissection, extending the dissection in some patients to N_3 and even N_4 nodes if necessary. In some cases a biopsy was taken from the para-aortic nodes (lymph node group No. 16). Immediately after the surgical procedure, the resected specimen was meticulously examined by the surgeon. All lymph nodes were dissected from the specimen and labelled according to the numbering system of the JRSGC (*Table 1*) Lymph nodes were examined histologically at three depths

Survival data were computerized every year after consulting the charts and the government registration statistics if data were missing There were no patients lost to follow-up Data were simply entered in an ASCII file database in a numbering system The program looks for specific numbering at certain locations within the ASCII string

Program

The program is written in MSDOS/Basic and was introduced in 1984 The program recalls and analyses, within only a few minutes, all cases that are similar to the patient in question. The computer identifies these patients by comparing the variables shown in *Figure 1* The first comparison is made on the basis of tumour location first, whether in the upper (C), middle (M) or lower (A) third and then whether in the lesser curvature (L), greater curvature (G), anterior wall (A) or posterior wall (P) The next branch choice is made according to the extent of invasion, then tumour classification, and finally the remaining variables are compared. When patients with the same variables are identified

and collected, survival rate, cause of death and lymph node involvement can be analysed. The rate of lymph node involvement is defined as the proportion of positive locations of lymph nodes at any one site. Five-year survival rate was calculated according to the life table method. Patients who died were placed into the following categories according to the cause of death: local recurrence, peritoneal or liver dissemination, distant metastasis, other cancer, other disease and surgical mortality.

Results

In this study 3843 patients entered the database of whom 3265 were resected with curative intent. For the group having curative resection, in almost all cases (96·5 per cent) the preoperative diagnosis and classification correlated with the surgical findings. The extent of invasion could be accurately assessed because of the expertise of the radiologists[14]. The location of the primary lesion was used as first selection criterion to collect cases similar to the patient in question; 742 cases were available with tumour located in the upper third, 1651 cases with tumour located in the middle third and 1450 cases with tumour located in the lower third of the stomach (*Figure 2*). After this preliminary division the computer program ran through the previously mentioned variables to pick up equivalent values.

To illustrate this process a real example will be given. The patient was a 58-year-old man who complained of epigastric pain and weight loss. After preoperative examination he was thought to have advanced gastric cancer type BIII, probably with involvement of the serosa (S2). The primary lesion was located in the lesser curvature of the body of the stomach. The diameter was estimated to be 5 cm and the biopsy result read 'poorly differentiated adenocarcinoma'. After these data have been entered in the database, the computer analysis is displayed on the screen, as shown in *Table 2*.

Since the beginning of 1984, prospective evaluation of the system based on clinical experience in approximately 1000 primary gastric cancer patients has proved encouraging, although this evaluation was not done with a protocol.

Discussion

Data management and computer analysis have been used in all types of studies, retrospective as well as prospective in design. More and more hospitals are computerizing their administration and patient data. This paper emphasizes the value of continuously registering cancer patients' data for future studies. In our study of gastric cancer patients, the computer has proved to be an important tool in preoperative decision-making. As all relevant data and results are readily available it is possible to make a well-founded decision concerning the extent of lymph node dissection required for an individual patient.

The debate concerning the removal of lymph nodes is heated. It is widely accepted that incomplete removal of the tumour at resection increases the likelihood of locoregional recurrence. On the other hand, the effect of local recurrence on the survival rate of gastric cancer patients is still a matter of discussion in western literature. In Japan, however, it is accepted among surgeons that suspect lymph nodes at least should be removed. The JRSGC even advocates the standard dissection of lymph nodes one 'level' further than the one involved. The benefit gleaned from the removal of lymph nodes beyond metastatic nodes is debatable. In order to minimize postoperative morbidity, it is important to limit the extent of surgery to what is still oncologically acceptable.

Several lymph flow studies have shown certain pathways and a suggested layering of lymph node groups according to the distance from the tumour[6,15]. More recent studies, on the other hand, have revealed that the route of metastasis is not fixed (Reference 16 and K. Ohta *et al.*, personal communication). N_2 and even N_3 nodes can be skipped to allow metastasis directly to para-aortic lymph nodes. In our series the macroscopic classification of lymph nodes differed from the histological classification in 38 per cent of the cases. Gall and Hermanek have also observed a higher rate of lymph node metastases than expected preoperatively, by using a more extensive dissection[17]. In patients operated on curatively, 10–25 per cent of the lymph node groups 7–12 were involved. These lymph nodes would not have been resected by conventional gastrectomy, and are therefore impossible to classify accordingly.

Ordinary decision-making is based on 'average experience' derived from large groups[18]. However, with the computer program described we can individualize the problem by differentiating between important prognostic variables for any one particular case. Outcome is assessed from a prospectively collected database and represents the clinical facts on metastases at specific lymph node locations. For every node location the percentage of metastases is given. It is postulated that at least removal of suspect nodes is necessary to improve survival results. We therefore feel confident in using our analysis to justify to what extent lymph node dissection should be performed. Standard procedures can be abandoned as we know, within statistical limits, which nodes will be involved in a specific individual case. This has already led to a less aggressive approach, concerning pancreaticosplenectomy in general and for individual lymph node locations more specifically.

In conclusion we would like to emphasize the indispensible value of computer programs and instant analysis in preoperative decision-making for surgeons dealing with cancer. It is essential for workers in each cancer field to agree on a uniform system of data management, based on uniform staging policies. We hope that this example will encourage efforts to standardize data management in surgical oncology.

Total gastrectomy and oesophagojejunostomy with linear stapling devices

B. S. Walther, T. Zilling, F. Johnsson, C. Staël von Holstein and B. Joelsson

Department of Surgery, Lund University, S-221 85 Lund, Sweden

Correspondence to: Dr B. S. Walther

When performing total gastrectomy and oesophagojejunostomy with a circular stapling device two disadvantages are obvious; firstly, a purse-string suture is needed, and secondly the instrument can be extremely difficult to introduce if the oesophagus is narrow, so that the risk of rupture is substantial. We therefore developed the following technique. When the specimen is attached only to the oesophagus, and the Roux-en-Y loop has already been divided with a linear stapling device, a small incision is made on the back wall of the oesophagus and antimesenterically 6 cm distal to the cut end of the Roux-en-Y loop. The two forks of the GIA® or the PLC 50® instrument are introduced into the oesophagus and jejunum, and the two organs are brought together at the hiatus. The instrument is closed and fired. The residual opening is closed with a linear stapler which also includes the front wall of the oesophagus. With a knife, the oesophagus and excessive amounts of tissue are trimmed away, and the oesophagojejunostomy is completed. Fifteen patients (median age 67 years) had a postoperative hospital stay of 10 days (range 8–45 days) after this operation. Leakage occurred in one patient and one patient died. The anastomosis took 12 min to perform (range 8–20 min). Three reoperations were needed: intestinal obstruction, leakage and a negative exploration. The median width of the oesophagojejunal anastomosis 6 months after operation was 32 mm (range 27–40 mm). Oesophagojejunostomy performed with two linear staplers allows a quick and reliable anastomosis independent of oesophageal lumen size and a time-consuming purse-string suture.

Keywords: Total gastrectomy, oesophageal anastomosis, stapling device

The main reason for postoperative mortality after total gastrectomy is still anastomotic leakage[1,2]. After the introduction of circular stapling devices the time to perform the oesophagojejunal anastomosis has been reduced, which is a substantial benefit in such time-consuming operations[3]. Recently it has been shown in a prospective study that the outcome for patients undergoing total gastrectomy was better after a stapled (EEA® stapler, US Surgical Corporation and Auto Suture UK, Norwalk, Connecticut, USA, or ILS®, Ethicon Ltd., Somerville, New Jersey, USA) oesophagojejunostomy than after a hand-sewn anastomosis[4]. There are, however, at least two disadvantages with circular stapling devices in constructing oesophagojejunal anastomoses. Firstly, a time-consuming purse-string suture is needed and, secondly, the insertion of the instrument into a narrow oesophagus can be extremely difficult and oesophageal rupture is described[3]. In an attempt to eliminate these drawbacks we have developed a new technique, using two linear stapling devices for the oesophagojejunal anastomosis, which is independent of a purse-string suture or other stay sutures and of oesophageal width. This article describes the surgical procedure in 15 consecutive patients undergoing total gastrectomy and chosen at random to have the new technique. The width of the oesophagojejunal anastomosis was measured after 6 months using a fibreoptic endoscope and a balloon, and the results were compared with those of patients operated on with a conventional end-to-side oesophagojejunostomy performed with a circular stapling device[3].

Patients and methods

From May 1986 to April 1988, eight men (median age 68 years, range 41–81 years) and seven women (median age 67 years, range 38–74 years) underwent total gastrectomy because of cancer (12), lymphoma (two) or gastrinoma (one). Five of the 12 cancer patients had previously had a Billroth II resection because of benign disease; six had their tumour confined to the body of the stomach and one to the cardiac region. Six patients had tumour growth penetrating the stomach, and lymph node metastases were present in five. The patient with carcinoma of the cardia had a liver metastasis.

Operative procedure

Total gastrectomy, with omentectomy, splenectomy, and dissection of the lymph nodes around the coeliac axis and hepatoduodenal ligament was performed in all patients. An extended procedure was performed in seven patients, including resection of the pancreatic tail in five, enucleation of a gastrinoma in the pancreatic head in one and a small bowel resection in another one. Of the 15 operations, 13 were performed using a laparotomy alone, and the remaining two were conducted through a left thoracoabdominal incision. All patients were given prophylactic antibiotics (400 mg intravenous doxycycline hydrochloride, Vibramycin®, Pfizer Ltd., Sandwich, UK). Dextran 70 (Macrodex®, Pharmacia, Uppsala, Sweden) was used as the antithrombotic drug.

At the end of the *en bloc* resection the specimen was attached only to the oesophagus and was brought up to the patient's chest (*Figure 1a*). A Roux-en-Y loop of 50 cm length was prepared and divided with a linear stapling device. A small incision was made on the back wall of the oesophagus, using the stomach for traction, and antimesenterically 6 cm distal to the closed end of the Roux-en-Y loop (*Figure 1b*). The two forks of the GIA® (US Surgical Corporation and Auto Suture UK) or the PLC 50® (Ethicon Ltd.) instrument were introduced into the oesophagus and the jejunum respectively, and the two organs were brought together at the hiatus (*Figure 1c*). The instrument was closed and fired (*Figure 1d*). After withdrawing the instrument the remaining opening was closed with a linear stapler, which also included the front wall of the oesophagus (*Figure 1e*). With a knife the oesophagus and excessive amounts of tissue were trimmed, and oesophagojejunostomy

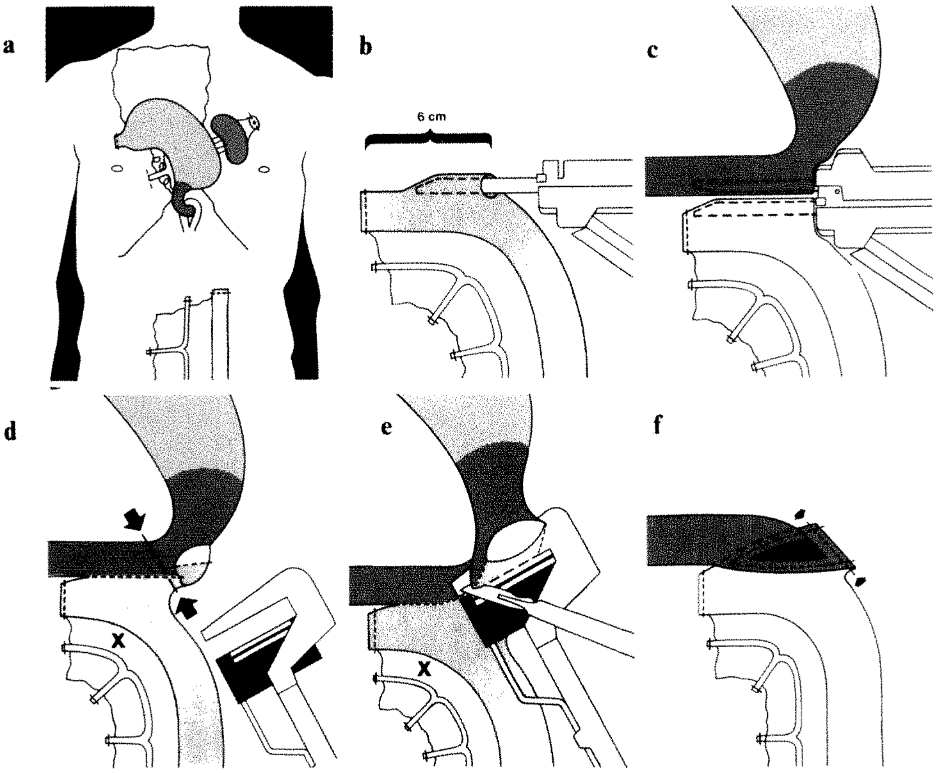

Figure 1a–f *End-to-side oesophagojejunal anastomosis after total gastrectomy with the PLC 50® or the GIA® and the RL 60® or the TA 55® stapling instruments. To avoid stapling the mesenteric border marked X* (**d, e**) *to the oesophagus, it is wise to insert the nasogastric tube before closing the residual opening*

was completed (*Figure 1f*). To accomplish the anastomosis in the left chest the specimen was brought up into the thorax through the hiatus and the anastomosis was completed in the same way as in the abdomen. When the opening after the GIA or the PLC 50 forks was closed with the TA 55® (US Surgical Corporation and Auto Suture UK) or RL 60® (Ethicon Ltd.) care was taken not to grasp the jejunal mucosa at the mesenteric border by pulling up too much of the jejunal lip (*Figure 1e*). On the other hand, it is important that the linear stapler encloses the staple lines of the GIA or PLC 50 instrument. This was facilitated by putting two Allis clamps one in each corner and 2–3 mm along the staple lines. With a slight lateral traction on the two clamps this manoeuvre also simplified closure of the opening by flattening it out. When a small piece of jejunum was seen on the specimen bridged to the oesophagus by cut staples and comprising a lumen, the anastomosis was considered to be intact. With the anastomosis under saline, integrity was checked by air inflation through the nasogastric tube. If a leak was present it was oversewn with an absorbable 4–0 suture. Otherwise no form of reinforcing stitches was used.

The time to perform the anastomosis (that is, the time from making the incisions in the oesophagus and jejunum to the closure of the oesophagojejunal opening with a linear stapling device (including the time to locate and oversew a leak) was measured by the anaesthetist. Frozen section examination of the resected margins was performed intraoperatively to ensure tumour clearance.

Postoperative regimen

The nasogastric tube was left with its tip well below the anastomosis, and the patient was fed intravenously for 5 days, after which the anastomosis was checked for leakage by X-ray films with water-soluble contrast medium. If no leakage was observed, the patient started to drink fluids, followed by a soft diet. On the seventh day, a regular diet was served and intravenous therapy was discontinued.

Follow-up

Six months after surgery nine patients were examined by endoscopy. The width of the anastomosis was calculated by inserting a Fogarty aortic occlusion catheter (American Edwards Laboratories, Irvine, California, USA) along with the endoscope. With a syringe connected to the catheter, air was inflated until the balloon in the distal end filled the anastomotic lumen. The balloon was pulled up and down a couple of centimetres to make sure that it was not getting caught but slid smoothly and just filled the anastomotic lumen. The volume inflated was noted on the syringe. This was repeated three times and the mean calculated. The air was exsufflated by pulling the piston of the syringe back but not disconnecting the syringe and the balloon catheter. After withdrawal of the endoscope and the balloon catheter, the latter was filled to the volume determined and the diameter of the balloon was measured with a caliper. This method of measuring the oesophagojejunostomy has been in use since 1984 in our department in a prospective series of patients having total gastrectomy and oesophagojejunostomy end-to-side with the EEA stapler. These patients served as controls when assessing the anastomotic width.

Statistical methods

The Kruskal–Wallis one-way analysis of variance by ranks was applied to test the difference between the three groups of stapled anastomoses. When a significant difference was noted, the Mann–Whitney *U* test was used to determine between which groups the difference was valid. When comparing two groups the Mann–Whitney *U* test was used directly.

Results

In all patients in whom we tried to perform the oesophagojejunostomy with the two linear stapling devices, we succeeded. To bring the oesophagus and jejunum together we used the GIA in 11 of the 15 patients and the PLC 50 in the remaining four. The residual opening was closed with the TA 55, staple height 3·5 mm (blue magazine), in nine patients and in six we used the RL 60, adjusted to the same staple height. The median operating time was 5 h 9 min (range 205–505 min) and the median time to perform the oesophagojejunal anastomosis was 12 min (range 8–20 min).

The postoperative complications are shown in *Table 1*. The patient who developed a leaking anastomosis was found to have no leakage on routine check of the anastomosis on the fifth postoperative day, but sudden onset of abdominal pain the day after made us explore the patient. The leakage was found in the corner between the two crossing staple lines. It was oversewn and drained and healed uneventfully within 2 weeks. The patient was discharged in good health after 28 days.

Table 1 *Postoperative complications and reoperations in 15 patients having total gastrectomy and oesophagojejunostomy*

	No.	Reoperations
Anastomotic leakage	1	1
Small bowel obstruction	1	1
Empyema	1	0
Lung embolus	1	1*

* This patient had a negative exploration and later died of a pulmonary embolus (hospital mortality one in 15)

The median postoperative hospital stay was 10 days (range 8–45 days). Extension of the operation by resection of the pancreas (six patients) increased the hospital stay to 13 days (range 8–36 days: Mann–Whitney $W=55$, $P=0{\cdot}44$, n.s.). Nine patients are alive 1·4–23 months after the operation.

At endoscopic examination 6 months after the operation the diameter of the oesophagojejunal anastomosis performed with two linear stapling devices was equal or superior to the EEA-stapled anastomoses (*Figure 2*). No patient complained of dysphagia.

Discussion

Oesophageal anastomoses with circular stapling devices must be considered safe when two large series report a leakage rate of 3·5 per cent[5,6]. There are, however, two main drawbacks: the need for a time-consuming purse-string suture and, in some cases, a narrow oesophagus; this can lead to a difficult and sometimes dangerous introduction of the instrument, which can result in oesophageal rupture[3]. Consequently many ingenious attempts have been made to facilitate the insertion of the anvil into the oesophagus. Alexander-Williams has proposed the use of a Mousseau–Barbin tube trimmed to cover the anvil; pulling the tube allows the anvil to be gently introduced into the oesophagus[7]. Chung *et al.* favoured dilatation of the distal oesophagus with a balloon catheter before insertion of the instrument[8]. However, none of these methods excludes the use of the purse-string suture. With this in mind we have been looking for a method that eliminates the need for a purse-string suture and the need for stay sutures or clamps in the oesophagus during the anastomotic procedure. We found the present method to be of great value in these respects because the size of the oesophagus is completely irrelevant.

It can be argued that in cases where there is a narrow oesophagus the oesophagojejunal anastomosis can be manually performed. There are, however, two arguments against this contention: time and standardization. The stapled anastomosis is quicker to perform than the hand-made anastomosis, both experimentally and clinically in randomized series, and reduction in overall operation time is relevant to the lower incidence of thromboembolic complications seen in stapled series[9,10]. Secondly, stapling instruments are unsurpassed for standardization, which is known to be an important factor for quality.

The time to perform the oesophagojejunal anastomosis with two linear staplers compares well with other staple methods, for instance oesophagojejunostomy end-to-side with a circular stapling device (12 and 20 min, respectively)[3]. The type and rate of complications seen in the present series are expected in this kind of surgery. What the leakage frequency will be in the long run cannot be predicted from this pilot series but our experience seems to correspond to that of others[1,2,11].

West *et al.* found stricture frequency to be inversely correlated to the size of the stapler in a series of patients having oesophageal resection and oesophagogastrostomy[12]. The true incidence of strictures in oesophageal anastomoses can be determined only by endoscoping all patients postoperatively, and Wong *et al.* have shown that most strictures are seen within 6 months[6]. It is well known that a narrow anastomosis can escape detection because of absence of dysphagia and conversely that the patient can complain of difficulty in swallowing with a wide anastomosis. The width of the oesophagojejunal anastomoses in the present series compares well with the circularly stapled anastomoses, particularly when one considers that patients operated on with linear staplers often include those with a very narrow oesophagus.

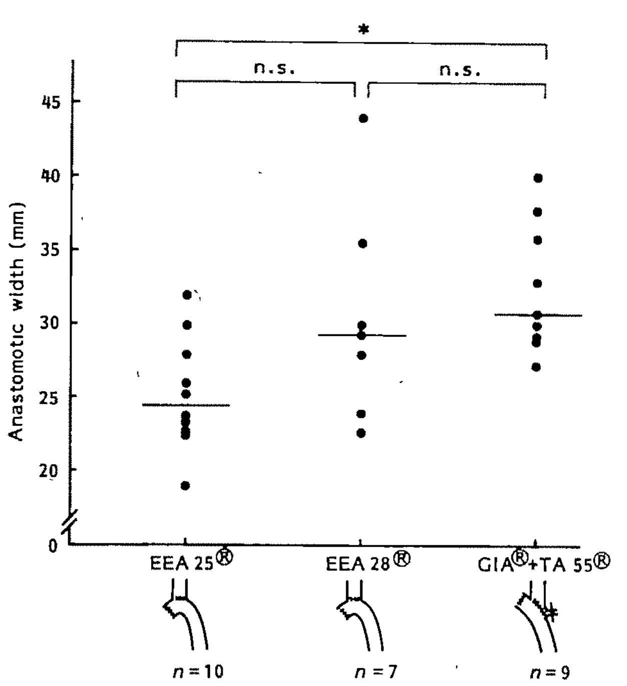

Figure 2 *The anastomotic diameter after 6 months in patients having total gastrectomy and different types of stapled oesophagojejunostomy Of the 15 patients operated on with the new method (GIA® + TA 55®) six patients were not investigated at 6 months postoperatively because three patients were dead or dying at that time, two refused investigation and one had not yet qualified Test for differences (see* Statistical methods) *EEA 28* versus *EEA 25 and GIA+TA 55, no significant difference; * EEA 25* versus *GIA+TA 55,* $P<0{\cdot}05$; ——, *median*

The anastomosis is partly inverted and partly everted with two corners of intersecting staple lines (*Figure 1f*) and hence there is a risk for ischaemia in that area. A large clinical experience attests, however, to the safety of intersecting staple lines both in intestinal and lung surgery, presumably owing to the fact that the blood flow continues through the intersecting staple lines[13]. None the less, the only leak in the present series arose in the corner of intersecting staple lines. Whether this was due to ischaemia or to technical failure could not be determined at relaparotomy. At the primary operation, 5 days earlier, however, the anastomosis was airtight under a pool of saline.

When the operation had to be extended to the left chest the anastomosis was easily completed in the same way as in the abdomen. However, we have no experience in performing a high oesophagojejunal anastomosis in the right chest with this technique. The curve always at hand at the end of a long jejunal loop fits better with the old end-to-side anastomosis where the circular stapler is introduced through the open jejunal end to the oesophagus[3].

Extension of the operation by resecting the pancreatic tail did not influence the postoperative hospital stay. This confirms the experience of Sadek *et al.*[14], but is in contrast to that of others[15]. As most surgery for gastric carcinoma is palliative, postoperative morbidity and mortality rates should be low and the hospital stay short. Dysphagia should be absent for the rest of the patient's life. We consider that oesophagojejunostomy performed with two linear staplers fulfils these demands in the present pilot study.

NdYAG laser treatment in the palliation of advanced oesophageal malignancy

A. Houghton, R. Mason, A. Allen and I. McColl

Department of Surgery, Guy's Hospital, St. Thomas's Street, London SE1 9RT, UK
Correspondence to: Mr A. Houghton

Carcinoma of the oesophagus is a common disease responsible for 3700 deaths per year in the UK[1]. Dysphagia is often the first symptom, by which time 50 per cent of patients are beyond the reach of curative surgery[2]. The results of surgery are poor although surgery has often been considered the best palliation[3]. The neodymium yttrium aluminium garnet (NdYAG) laser has considerably advanced the management of this condition and is suggested to be associated with lower mortality and morbidity rates than various forms of stenting tubes[4]. This paper describes the results with our first 51 patients.

Patients and methods

Fifty-one patients with malignant strictures of the oesophagus were investigated. The male:female ratio was 1·7·1 and the median age was 76 years (range 49–92 years). Seventy-five per cent of patients were older than 70 years. All patients had positive histology before treatment: 43 had adenocarcinomas and eight had squamous carcinoma. The strictures commenced between 18 and 40 cm with a median length of 5 cm (range 2–14 cm). The adenocarcinomas commenced between 28 and 40 cm and the squamous tumours proximal to 30 cm. All patients were considered inoperable because of age, concomitant disease, generalized metastases or advanced local disease on computed tomograpic scan Swallowing was assessed by an independent observer before and after treatment. The 'dysphagia index' was assessed according to ability to swallow: 0, all solids, 1, most solids, 2, semisolids; 3, fluids, 4, nothing[6]. All procedures were performed under intravenous sedation with diazepam using the Olympus GIF 2T10 (Olympus Ltd., Tokyo) twin suction channel endoscope. A NdYAG laser of wavelength 1064 nm was used. A non-contact method was employed where possible with a power of 70 W for 1 s and a total energy dosage between 5000 and 10 000 J per treatment An average of two sessions separated by 72 h was required to open a satisfactory lumen. Treatment was repeated after 1 month and the rate of tumour progression was assessed at that stage. Follow-up treatments were performed at intervals of 3–12 weeks dependent upon progression of tumour and recurrence of symptoms.

Results

In all 166 treatments were given, an average of 3·3 per patient. On 34 occasions wire-guided dilatation with Celestin® (Medoc, Gloucester, UK) bougies was necessary. On 17 occasions a guidewire would not pass and the direct contact sapphire-tipped laser endoprobe using a power of 15 W was required to create a lumen.

The dysphagia indices before and after treatment are shown in *Figure 1*. Three patients failed to complete the first course of treatment:, two died of aspiration pneumonia and one was perforated at dilatation. In 44 of the remaining 48 cases swallowing was improved. This improvement in median dysphagia index from 3 to 1 is significant ($P<0\cdot0001$, Mann–Whitney U test). The long-term results in patients surviving more than 2 months are shown in *Figure 2*. Swallowing was significantly improved over pretreatment values at 2, 4 and 6 months ($P<0\cdot0002$). Of the 51 patients, 24 died in the first 2 months, and six and three died before 4 and 6 months respectively. Of the six patients surviving longer than 6 months, five have now died within 6–9 months of their first treatment with dysphagia indices of 0–2, and one is still alive with a dysphagia index of 1 after 6·5 months. Three patients, after surviving for 2, 2 and 6 months respectively, developed rapid progression of symptoms owing to circumferential tumour stenosis with extrinsic compression. Laser therapy produced only transient relief of symptoms and endoscopic intubation with an Atkinson® tube (Key Med, Southend-on-Sea, UK) was necessary. With the exception of two individuals who were lost to follow-up the remaining eight patients are alive and under review at a median time of 3 weeks (range 1–12 weeks) after their first treatment.

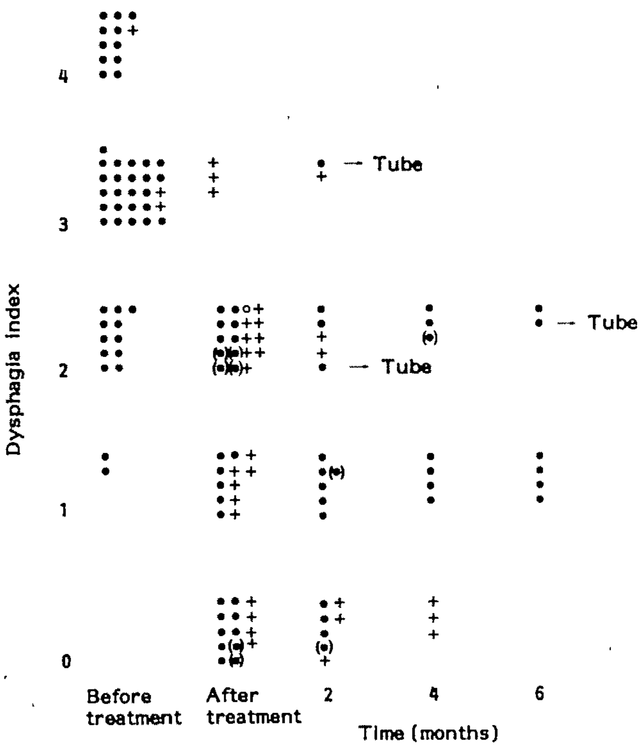

Figure 2 *Long-term results of laser treatment. Dysphagia index assessed as ability to swallow 0, all foods, 1, most solids, 2, semisolids, 3, fluids; 4, total dysphagia.* ●, *Individual patients,* (●), *patient alive but has not reached next stage;* O, *patient refused follow-up,* +, *death before completing the next stage. Position of cross shows the dysphagia index at the last completed stage before death. At death most patients were taking a solid or semisolid diet*

There was one perforation due to dilatation and one suspected perforation due to the laser in this series. Symptoms of reflux oesophagitis were common and Gaviscon® (Reckitt and Colman, Hull, UK) treatment was helpful.

Discussion

Both palliative and 'curative' surgery for carcinoma of the oesophagus carry high risks of morbidity and mortality and 80 per cent of patients are dead within 1 year[5]. Our results suggest that good palliation of dysphagia with minimal morbidity and mortality can be achieved with the laser and are in agreement with data from other workers[6-8]. Not all patients can be kept swallowing with laser therapy and 6 per cent required intubation in this series. In one patient satisfactory swallowing was maintained for 6 months before intubation became necessary.

A major problem in this condition is the impassable stricture. In these cases direct contact laser therapy offers a good method of opening up the stricture. This is in agreement with results from a previous study[9] but in our hands does not require a general anaesthetic.

In conclusion the laser offers a safe method of palliation in patients with malignant obstruction of the oesophagus. As the results of surgery for carcinoma at this site are so poor we would recommend that patients fit for surgery are initially assessed using a computed tomographic scan[10]; those shown to have advanced disease on scanning, elderly patients and those unfit for surgery are best treated by laser therapy.

A retrospective study was performed on gastric cancer patients admitted to the Cancer Institute Hospital, Tokyo, during the periods 1961–65 (n = *1181*) *and 1980–84* (n = *1473*)*. The aim of the study was to see whether changes had occurred in gastric cancer patients over the years with respect to histology and tumour localization and, if so, how they compared with reports from the West. The proportion of proximally localized primary tumour increased from 17 to 27 per cent* ($P=0{\cdot}008$)*, and signet-ring cell carcinoma increased from 2 to 22 per cent* ($P<0{\cdot}001$)*. These changes were not relative with regard to the declining incidence of intestinal tumours, but absolute. Patients with proximally localized tumours were generally in a more advanced stage of disease than those with distally localized tumours, and thus had poorer survival rates. However, after stratifying into stages, the difference in survival disappeared. The survival rate of patients with signet-ring cell carcinoma was not significantly different from that of patients with other gastric tumours* ($P>0{\cdot}05$)*. The discrepancy between the survival rates of Japanese and western gastric cancer patients is attributed by some authors to tumour-related factors. However, we believe that the similar trends found with regard to tumour localization and histology point towards comparable tumour behaviour in the two different geographical areas.*

Keywords: Gastric carcinoma, histology of gastric cancer, tumour localization in gastric cancer, tumour behaviour

It is well established world-wide that the incidence of gastric cancer is declining but this trend has been observed only recently in Japan. Other trends are occurring and several reports from western countries indicate changes in the localization and histology of gastric adenocarcinoma[1–5]. The incidence of tumours in the proximal stomach seems to have increased in comparison with distal locations. A reason for this has not yet been found, but it has been suggested that if the intestinal form of adenocarcinoma, which occurs most often in the distal stomach, is decreasing, this would cause a relative change. Changes in histology have also been observed when comparing data from the 1950s and the 1980s[2,3]. Recent studies report a higher incidence of signet-ring cell carcinoma.

We considered that these trends were important when attempting to identify any differences in the features of gastric cancer in Japan compared with the West. The present study was mounted at the Cancer Institute Hospital, Tokyo, to describe changes in Japan and to determine whether the biological behaviour of tumours explains the discrepancy in survival results between Japan and the West.

Patients and methods

All patients who underwent an operation for gastric cancer in the Cancer Institute Hospital, Tokyo, during the two 5-year periods 1961–65 ($n=1181$) and 1980–84 ($n=1473$) were reviewed. In 145 and 77 patients, respectively, some histological data were missing because only laparotomy or bypass anastomosis was performed. These patients were excluded from the analysis leaving 1036 and 1396 patients in the study.

Localization

Firstly, all patients, early as well as advanced cases, were analysed for tumour localization and stage of disease; the mean age and the male:female ratio were calculated. Patients were classified according to tumour localization as follows: C, upper third; M, middle third, A, lower third of the stomach. The upper division line was set 5 cm distal to the oesophageogastric junction. As we wished to make a comparison with western reports, a separate analysis was done of patients with advanced gastric cancer, i.e. tumour invasion beyond the submucosa. Tumour localization, mean age and male:female ratio were again determined for the two periods and a further analysis was performed.

Histology

Patients with advanced gastric cancer from both groups were analysed with regard to the histological reports All specimens had been examined histologically at the Department of Pathology of the Cancer Institute Hospital, Tokyo. Patients were placed into categories on the basis of the following histology: well differentiated, poorly differentiated, and signet-ring cell adenocarcinoma. Other types of histology were ruled out. The diagnosis of signet-ring cell carcinoma was made if more than 50 per cent of the tumour cells were characteristic, i.e. numerous mucin vacuoles that may distend cells or may coalesce and compress the flattened nucleus against the plasma membrane. The criteria were not changed during the periods in question. For those patients with signet-ring cell carcinoma, age, sex distribution and localization of primary tumour were determined separately for the two periods, and then compared.

Statistics

χ^2 analyses were employed for the comparison of individual variables. The patients operated on from 1980 to 1984 were stratified in stage groups according to the new TNM (UICC tumour node metastasis) system. To establish any relationship between location or signet-ring cell carcinoma and stage of disease, the proportion of patients with C location and signet ring cell carcinoma was calculated as a percentage of the entire group of 1980–84 patients, including patients with early as well as those with advanced gastric cancer Surgical mortality was defined as death within 30 days of operation.

Results

An increase in the proportion of early gastric cancers was seen in the second period (*Table 1*), in most cases these occurred in the body of the stomach. Age and male:female ratio did not change significantly between the two periods ($P>0{\cdot}05$ and $P>0{\cdot}1$ respectively).

All early gastric cancer patients (i.e. tumour restricted to the (sub)mucosa independent of lymph node involvement[7]) were then excluded, leaving two groups of patients with advanced cancer for further analysis; there were 865 and 811 patients from the 1961–65 and 1980–84 periods respectively. The incidence of proximally situated advanced gastric

	Operation period	
	1961–65 (*n*=1036)	1980–84 (*n*=1396)
Age (years)		
Mean	55·8	56·2
Median	57·2	58·1
Sex (M:F ratio)	1·76	1·93
Early cancer	171 (16·5)	585 (41·9)
Advanced cancer	865 (83·5)	811 (58·1)

Values in parentheses are percentages

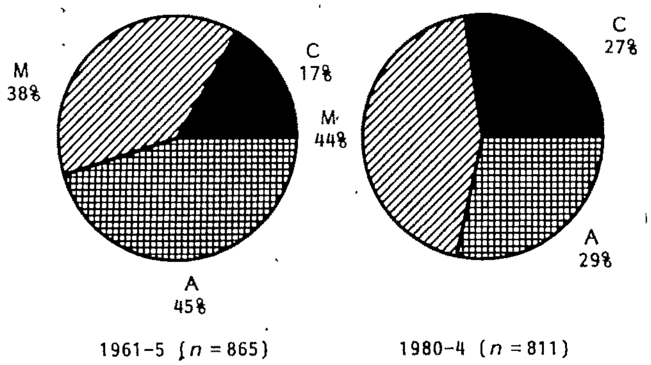

Figure 1 *Location of advanced gastric cancer in the two periods. C, upper third; M, middle third; A, lower third*

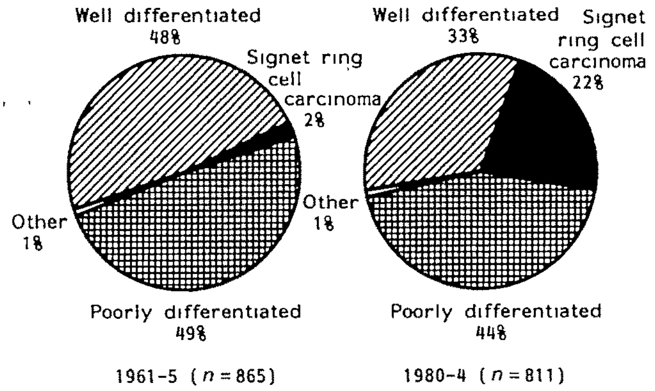

Figure 2 *Histology of advanced gastric cancer in the two time periods*

adenocarcinoma increased from 17 to 27 per cent, which is a statistically significant change (*Figure 1*; $P=0{\cdot}008$). The mean age of patients with advanced disease increased from 55·4 years (median 57·2 years) to 58·1 years (median 59·6 years; $P=0{\cdot}1$) and the male:female ratio decreased from 2·43 to 1·96 ($P=0{\cdot}08$).

Subsequently we compared the histological results between the two groups of patients with advanced gastric cancer. Signet-ring cell carcinoma was diagnosed in 2 per cent ($n=19$) of the patients in the first period and in 22 per cent ($n=178$) in the second period (*Figure 2*; $P=0{\cdot}0001$). Although the group of patients with signet-ring cell carcinoma was too small to make a reliable statistical calculation, it seemed that the mean age within this group had decreased from 57·2 to 51·7 years ($P>0{\cdot}05$). The male:female ratio change was not significant, rising from 0·73 to 0·94 ($P>0{\cdot}05$).

Figures 3 and *4* show the stage grouping for C location and signet-ring cell carcinoma for the period 1980–84. Proximally located tumours were generally diagnosed in a more advanced stage of disease than distally located tumours and thus have poorer survival rates. The operative mortality rate was 0·87 per cent in the group with proximally located cancer, compared with 0·45 per cent in those with more distally localized tumours. There was no relationship between histology and the stage of disease in patients with signet-ring cell carcinoma (*Figure 4*).

Discussion

Proximally located gastric cancer has been diagnosed more frequently in recent years; an average increase from 10 per cent to 40 per cent has been reported in the last three decades[2–4]. In the present study, it was decided to exclude early gastric cancer patients from the analysis for two reasons: firstly, in western and other 'low incidence' countries, where double contrast radiographs and gastroscopy are not used as frequently as in Japan, only 2–6 per cent of diagnosed cases are early gastric cancers, whereas in Japan early gastric cancer accounts for 41 per cent of the cases[1,5]. Secondly, as reported by Sasse *et al.*[5], and confirmed in our study, early gastric cancer is detected relatively less frequently in the proximal stomach than in more distal locations. However, it cannot be concluded that early gastric cancer is merely confined to distal locations, as the determination of early gastric cancer in the proximal stomach is technically difficult[8]. Therefore, an analysis using only patients with advanced cancer will exclude any bias caused by detection problems and thus be more comparable with western reports.

In the Cancer Institute Hospital, Tokyo, we have also found

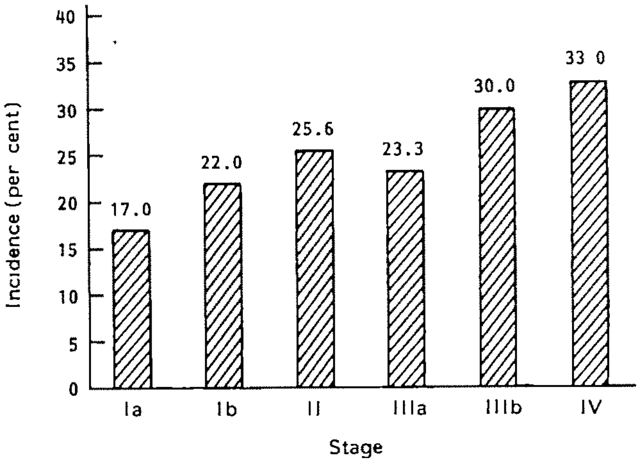

Figure 3 *Relationship between stage of gastric cancer and incidence of upper third location. The exact percentages are given for each stage*

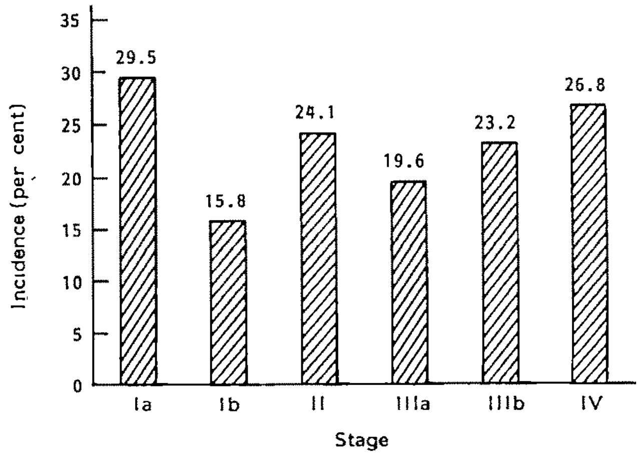

Figure 4 *Relationship between stage of gastric cancer and incidence of signet-ring cell carcinoma. The exact percentages are given for each stage*

an increased incidence of proximally located cancer, although the change is not as marked as in western series. So far no explanation has been found. Two previous reviews[4,5] suggest that it is a matter of relative change, as the incidence of distal, intestinal type tumour[6] is declining. We also observed a decreased incidence of antral tumours from 45 to 29 per cent, but the increase of proximally located tumour was absolute, rising from 144 to 222 cases (from 17 to 27 per cent) despite a small fall in the population of patients with advanced gastric cancer. Meyers *et al.*[3] suggested that specific dietary carcinogens may induce cancer at different locations. Although diet certainly influences the occurrence of gastric cancer, no evidence has been offered as yet to support specific, location-bound induction within the stomach. Another hypothesis is that of inherited genetic susceptibility, an hypothesis supported by observed racial differences[9]. In our study all patients were from a homogeneous occidental population, and therefore we were unable to examine this proposal. The male:female ratio decreased to about 2·0, which is in contrast with several publications that report a far greater male predominance[1,2] The increased mean age of 58·1 years in the second period corresponds with that reported in other publications[1–3].

The second change in gastric cancer was the observation of a higher incidence of signet-ring cell carcinoma. The diagnosis is, in part, dependent on two subjective judgements. Firstly, the more advanced the tumour, the more difficult it is to make a definite diagnosis; the characteristic mucin and trabecular system seem to be less clear the more the tumour invades the gastric wall[10]. Secondly, the decision to make the diagnosis of signet-ring cell carcinoma depends on the percentage of characteristic tumour cells that is set as a criterion by the individual pathologist. If we overlook these definition problems, an increasing number of patients with signet-ring cell carcinoma has been noted[2]. By setting the criterion for diagnosis at 50 per cent characteristic cells, we also found a significant increase (of up to 22 per cent) in the proportion of signet-ring cell carcinomas and a predominance in distal locations. The male:female ratio did not change significantly, but was low when compared with other publications.

Our study shows that patients with proximal gastric cancer have a worse prognosis than those with a more distally located tumour. However, after stratification the difference disappears, implying that proximally located tumours are generally found at a later stage of disease. This agrees fully with the concept that detection of early cancer in the proximal stomach is mainly a technical problem. For signet-ring cell carcinoma, the survival rates were not statistically different from those of patients with poorly or well differentiated adenocarcinoma. This agrees with the study of prognostic factors in gastric cancer by Maruyama and Miwa[11], in which histology is awarded a relative risk factor of only 1·16 using Cox's proportional hazards model. On the other hand, some signet-ring cell carcinomas may be of parietal origin, carcinomas that are thought to carry a different prognosis.

In conclusion, we have found similar trends in the gastric adenocarcinoma patients at the Cancer Institute Hospital, Tokyo, as have been found in several western populations. It would be more appropriate to compare population-based data but, from the present study, it seems that similar trends in localization and histology are occurring in gastric cancer patients, in low- as well as high-incidence countries.

Correspondence to: Dr A. Bianchi, Cardona Calle Madrazo 24-26 3°-2ª, 08006 Barcelona, Spain

Perforation of a colonic interposition for oesophageal stenosis has not been previously reported after ingestion of aspirin. We present a patient in whom conservative management was successful.

Case report

A 33-year-old man with a long-standing history of oesophageal stenosis due to gastroesophageal reflux and four previously unsuccessful operations, underwent resection of the oesophageal stenosis with a left isoperistaltic coloplasty in 1979. In June 1988 the patient was involved in an accident while manipulating a fire-work rocket. As a result, he developed a painful lesion in the left hand and started taking analgesics (2–4 g/day acetylsalicylic acid). In August he noticed the acute onset of epigastric discomfort and pain in the right posterior hemithorax; 7 days before admission he passed black-tarry stools.

On admission the patient was haemodynamically stable, with epigastric pain. Rectal examination confirmed black-tarry stools. The haemoglobin was 9·5 g/dl and the white blood count $9{\cdot}5 \times 10^3$/dl. The electrocardiogram showed a sinus tachycardia of 160 beats/min. The chest X-ray showed surgical changes in the right hemithorax, while the plain abdominal films were normal. Twelve hours later severe respiratory distress developed with a fever of 39·5°C. He was admitted to the intensive care unit. Chest X-ray revealed an infiltration in the right lung, and a rise in the white cell count ($12{\cdot}2 \times 10^3$/dl) was noted. Seventy-two hours later there was evidence of progressive lung consolidation with cavitary lesions in the pleural space and mediastinum that were confirmed by computed tomographic (CT) scan. A barium swallow showed a leak in the lower third of the intrathoracic colon, with free barium above the right hemidiaphragm (*Figure 1*). An upper gastrointestinal endoscopy showed abundant pus and mucus in the colonic mucosa but the perforation could not be visualized.

Antibiotic therapy was started with clindamycin and tobramycin, and parenteral nutrition was initiated. A large chest tube was placed under CT scan guidance in the largest cavity, but the fever persisted and a repeat CT scan revealed another large posterior cavity; this was also drained percutaneously. His clinical condition improved subsequently, and a further Gastrographin® (Schering, Berlin, GDR) swallow showed no evidence of leakage. On day 45 the chest tubes were removed and oral feeding was started.

Discussion

The development of fistulae in oesophageal surgery is a common complication in the postoperative period[1] but the late presentation in this case is a rare finding[2]. The most probable cause was the development of an ulcerative lesion in the colonic mucosa, secondary to the massive intake of aspirin. The ulcer was not seen on endoscopy but it seems reasonable to assume that the erosive effect of salicylates[3], potentiated by the stasis that frequently occurs after a coloplasty[4], triggered perforation in the colonic mucosa. The clinical picture of pain and upper gastrointestinal bleeding, followed by the development of intrathoracic leakage with pleural and mediastinal abscesses, substantiates this hypothesis.

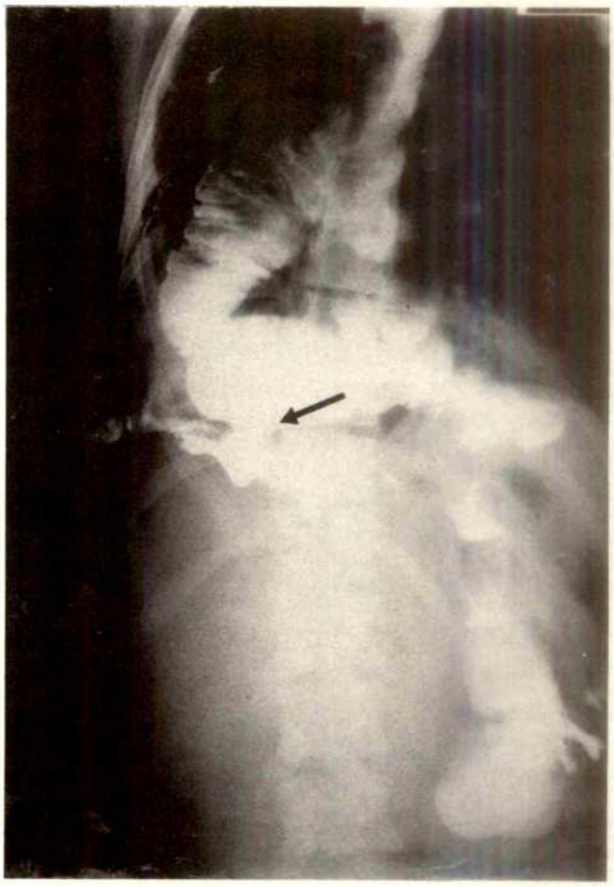

Figure 1 *Barium extravasation from coloplasty with contrast medium above the right hemidiaphragm (arrow)*

The early introduction of parenteral feeding and the percutaneous drainage of the thoracic purulent collections with appropriate antibiotic cover were followed by a remarkable clinical improvement and resolution. We believe that this conservative approach spared the patient a complicated surgical procedure, the outcome of which was uncertain because of his critical condition and previous history of multiple thoracic and abdominal operations.

Emergency subtotal oesophagectomy

H. R. Matthews,
I. M. Mitchell and
J. A. McGuigan

Regional Department of Thoracic Surgery, East Birmingham Hospital, Bordesley Green East, Birmingham B9 5ST, UK

Correspondence to:
Mr H. R. Matthews

From 1981 to 1987 nine patients have undergone resection and reconstruction of the oesophagus as an emergency, using a two-part left-sided approach with oesophagogastric anastomosis in the neck. Five patients had oesophageal perforation with a carcinoma; one had spontaneous perforation of an intrathoracic stomach; two had severe haemorrhage; and one had acute sterile mediastinitis. Following operation there was one postoperative death (11 per cent) and no major complications. Long-term survival was marred only by the development of further malignancy in four patients. Subtotal oesophagectomy has both theoretical and practical advantages over conventional oesophagogastrectomy in oesophageal emergencies and we suggest that it should be considered as the method of choice in the management of these difficult cases.

Keywords: Oesophageal perforations, carcinoma, resection

Management of the patient who requires oesophageal resection as an emergency presents a number of singular and sometimes refractory difficulties. Such patients are frequently in shock, with gross pleural or mediastinal contamination from oesophageal leaks, and some are elderly and have significant associated cardiac or pulmonary disease. Frequently, the oesophageal diagnosis is incomplete, particularly with respect to the presence or absence, nature and extent of pre-existing conditions (such as tumour, stricture or motility disorders), and even the size and location of perforations may not have been clearly defined.

In these circumstances the surgical approach must make it possible to deal with a wide variety of operative findings, and we have therefore preferred a two-part left-sided subtotal oesophagectomy with cervical oesophagogastric anastomosis, as recently described for the elective resection of oesophageal carcinoma[1]. In the past 7 years we have used this procedure on nine critically ill patients in our unit, and the purpose of this paper is to present our results and discuss the merits of this approach in the treatment of oesophageal emergencies requiring resection.

Patients and methods

From January 1981 to December 1987 a total of 318 oesophageal resections were performed under the care of the senior author (H.R.M.), of which nine (2·8 per cent) were done as an emergency. The ages of the patients ranged from 27 to 71 years (mean 54 years) and six were men; clinical features are summarized in *Table 1*.

Six patients had gross mediastinal and pleural contamination from intrathoracic leaks. Five of these were the result of endoscopic perforation (four from outside units, one from our own) and all had an underlying carcinoma, although this was not recognized until operation in two patients. The sixth patient had undergone an intrathoracic Nissen fundoplication for short oesophagus and reflux stricture 3 months previously at another hospital and was admitted in profound shock with spontaneous necrosis and perforation of the gastric fundus into the left chest. Owing to delays in diagnosis and transfer to our unit, three of these patients were not operated on until 24 h after the perforation, the others being operated on at 8, 12 and 14 h respectively; for this group of six patients the mean interval from perforation to operation was 18 h.

Two patients were resected for severe haemorrhage. The first of these (No. 7) had oesophageal varices and portal hypertension from chronic active hepatitis B and had been treated by sclerotherapy for recurrent bleeding on at least ten occasions during the preceding 14 months. He was admitted on this occasion with further severe bleeding which failed to respond to treatment, including the use of a Sengstaken–Blakemore tube. He had already been referred to another hospital for possible oesophageal transection but was considered to be unsuitable for this because of dense oesophageal fibrosis from his repeated sclerotherapy, and oesophageal resection was therefore preferred. The second patient (No. 8) was admitted with acute haemorrhage from a Barrett's ulcer in a columnar-lined oesophagus, with associated hiatus hernia and gastro-oesophageal reflux; conservative treatment was unsuccessful and operation was performed after transfusion of 13 units of blood.

The remaining patient (No. 9) presented an unusual problem: having been perfectly well for 3 days after oesophagoscopy and dilatation for chronic oesophageal ulceration and stricture he suddenly developed severe central chest pain and vomiting, with shock. A postemetic rupture was suspected but a Dionosil® (Glaxo Laboratories Ltd., Greenford, UK) swallow showed no evidence of rupture or perforation, and exploration was performed. This revealed a chronic penetrating ulcer which was densely adherent to the mediastinal connective tissue with an associated short oesophagus and reflux stricture. There was no free perforation of this ulcer but the mediastinal tissues around it were grossly oedematous. It was postulated that the original dilatation of the stricture may have aggravated the reflux, leading to inflammation in the base of the ulcer and an acute sterile mediastinitis.

Excluded from this study are 12 patients with intrathoracic perforation of the oesophagus who were seen during the same time period but who were managed without resection. Three of these patients (with terminal carcinoma) received no active treatment, eight were treated by conservative means, with or without chest drainage, and one was treated by operative repair.

Perioperative management

Before operation all patients received intravenous fluids (electrolyte, colloid or blood) and one required vasopressors, but operation was not delayed even if a normal circulation could not be restored. Antibiotics were administered before operation in the six patients with leaks, and at the time of induction of anaesthesia in the other three patients. Radiological contrast studies were obtained as an emergency in five patients, but were omitted in two patients who were too ill and in the two bleeding patients who had already had them. Emergency endoscopy was not performed in any patient, but the chest was drained before induction of anaesthesia in all patients with a pneumothorax or hydrothorax.

Subtotal oesophagectomy was performed in all patients through a left thoracolaparotomy in the sixth intercostal space, followed by an oblique left cervical incision, as previously described[1]. After mobilization of the thoracic oesophagus the cardia was divided and closed and the stomach was mobilized fully, preserving only the right gastroepiploic vessels and their associated arcades. Posterior pyloromyotomy was performed for gastric drainage and the elongated stomach was then positioned in the mediastinum, medial to the aortic arch and up to the apex of the chest, with end-to-end anastomosis of the stump of the oesophagus to the fundus of the stomach through the cervical incision. Two patients were found to have complicating factors in the form of a benign gastric ulcer in one case and a colloid goitre in another, but neither of these prevented satisfactory completion of the operation.

Table 1 *Clinical features of patients having emergency subtotal oesophagectomy from 1981 to 1987*

Patient no.	Age (years)	Sex	Pre-existing condition	Emergency indication	Time from perforation to operation (h)	In-hospital stay (days)	Outcome
1	67	M	Adenocarcinoma cardia Node positive	Endoscopic perforation (rigid)	24	27	Died at 8 months Recurrence
2	71	F	Squamous carcinoma lower third Node negative	Endoscopic perforation (flexible)	24	24	Died at 4 years 9 months Primary pelvic adenocarcinoma
3	48	F	Squamous carcinoma middle third Node positive	Endoscopic perforation (flexible)	24	—	Died on third postoperative day
4	53	F	Squamous carcinoma middle third Node negative	Endoscopic perforation (flexible)	8	11	Alive at 2 years 7 months Recurrence
5	48	M	Adenocarcinoma lower third Node negative	Endoscopic perforation (rigid)	14	14	Alive and well at 9 months
6	42	M	Intrathoracic Nissen fundoplication	Spontaneous intrathoracic gastric perforation	12	23	Alive and well at 2 years
7	27	M	Oesophageal varices, portal hypertension	Haemorrhage	—	10	Alive and well at 2 years No further bleeds
8	66	M	Barrett's ulcer, columnar-lined oesophagus	Haemorrhage	—	22	Died at 2 months Malignant hepatoma
9	60	M	Penetrating ulcer, hiatus hernia, reflux	Acute sterile mediastinitis	—	16	Alive and well at 9 months

One patient (No. 6) had to have an area of gastric necrosis adjacent to the cardia resected with a cuff of stomach, but gastric resection was not performed in any other patient. In the patient with oesophageal varices (No. 7) splenectomy was performed for a grossly enlarged spleen.

After operation, patients were ventilated only if their spontaneous respiration was unsatisfactory. Nasogastric tubes were not used in any patient, but one (No. 6) had a small Foley catheter inserted across the neck, as a temporary gastrostomy, to decompress the stomach which was severely inflamed. Oral fluids were commenced from the second postoperative day, as soon as the patients' general condition permitted, and they then progressed to soft diet by the time of discharge from hospital. Parenteral nutrition was not routinely employed. Antibiotics were continued after operation in those patients who had intrathoracic contamination at the time of surgery.

Results

Early results (Table 1)

Of the nine patients, eight made a satisfactory recovery and one (No. 3) died on the third postoperative day from renal failure and irreversible shock, having required vasopressors even before operation. Autopsy by the coroner's pathologist confirmed death from circulatory failure with no evidence of residual tumour; the oesophagogastric reconstruction was healthy and intact. Two patients required ventilation for 3 and 11 days respectively (the latter requiring tracheostomy) and one patient developed sputum retention on the second postoperative day and was treated by minitracheotomy and high-frequency jet ventilation[2] for 8 days with a good recovery. One patient was found to have a localized anastomotic leak on routine postoperative barium studies but was asymptomatic and no treatment was required. No other complications occurred. Inpatient stay ranged from 10 to 27 days with a mean of 18 days.

Late results (Table 1)

Of the four surviving patients with perforated carcinoma, one died at 8 months from recurrence, one died at 4 years and 9 months from a primary pelvic tumour (of different histological type), one is alive at 2 years 7 months with recurrence, and one is alive and well at 9 months. Of the patients with non-malignant disease, one died at 2 months from a primary hepatoma that was not diagnosed at the time of operation, and the remaining three are alive and well from 9 months to 2 years after operation. One patient had temporary mild dysphagia which required anastomotic dilatation, but no other complications referable to the operation have developed and no surgical revision has been required.

Discussion

In this paper our main concern has been with the management of those oesophageal emergencies that are bad enough to require immediate resection. It is well recognized that some cases of oesophageal perforation, for example, can be treated successfully without resection, but this is generally not the case when there is carcinoma and a free connection between the oesophageal lumen and the pleura, as in five of the six patients with perforation in this series. In these cases the principle of immediate resection and reconstruction has become well established since the first such procedure was reported by Satinsky and Kron[3,4], although initial resection (with oesophagostomy and gastrostomy) followed by delayed reconstruction may be safer in late cases with gross mediastinal infection[5,6].

Most of the immediate resections and reconstructions reported, however, have consisted of a conventional oesophagogastrectomy, removing only the lower oesophagus and upper stomach, with an intrathoracic anastomosis below the level of the aortic arch. While the results with this procedure have generally been reasonably satisfactory it does have certain limitations. Firstly, it does not give very good lymphatic clearance in patients with carcinoma; secondly, in cases with mediastinitis the anastomosis has to be constructed using inflamed oesophagus in a potentially infected field, which may well predispose to serious postoperative leaks[7]; thirdly, if patients do survive long-term then they are liable to have significant symptoms or complications from reflux[4]; and fourthly, the procedure is not suitable for lesions higher in the oesophagus.

Oesophagogastric anastomosis in the neck overcomes these difficulties. Longitudinal clearance of tumours is clearly better, which may improve the prospects for long-term survival[1], and the anastomosis is constructed in a relatively clean field using healthy proximal oesophagus, which is well vascularized and not oedematous or inflamed. Reflux is less likely to occur than with an intrathoracic anastomosis because of more favourable transanastomotic pressure relationships[8], and the procedure is applicable to lesions at any level in the thoracic oesophagus. From the technical point of view anastomosis in the neck is actually easier than in the chest, as the two ends are delivered and joined outside the cervical wound and not at the bottom of a deep thoracic cavity. In our patients we found no difficulty in getting the stomach to reach to the neck, despite the presence of a gastric ulcer in one patient and a gastric perforation in another, and the use of a cervical anastomosis did not increase the length of the operation as the intrathoracic part was correspondingly shorter.

In a few patients supra-aortic or 'high' intrathoracic anastomoses have been reported, using stomach[3,9,10] or colon[11], and Larsson and Pettersson[5] have stressed the importance of a high anastomosis in diminishing postoperative reflux, but the routine use of a cervical anastomosis for emergency resections has not apparently been proposed. Our results would suggest that such a policy merits serious consideration. Apart from one postoperative death from irreversible shock, the early results have been excellent and the long-term outcome has been marred only by the development of further malignancy (either primary or secondary). In some circumstances (e.g. late cases with gross infection) immediate reconstruction is not advisable, and the neck should be opened to construct a terminal oesophagostomy and defunction the mediastinum. In cases that are suitable for immediate resection and reconstruction, we would suggest that the neck should be used as the preferred site for the construction of the anastomosis.

Laser angioplasty with a pulsed NdYAG laser: early clinical experience

Since December 1986, 40 laser angioplasty procedures have been performed using the energy from a pulsed NdYAG laser, delivering near infrared light (1064 nm) in 100-μs pulses of approximately 300 mJ per pulse, directly through a transparent sapphire tipped device. All patients had total occlusion of the superficial femoral artery and symptoms severe enough to warrant surgery, with ulceration or gangrene in eight, rest pain in 14 and severe claudication interfering with life-style in the others. The device was introduced through an antegrade puncture of the superficial or common femoral artery and laser recanalization was followed by attempted balloon angioplasty in all cases. Occlusions were a median length of 15 cm (range 2–35 cm); ten patients had previously undergone failed attempts at conventional balloon angioplasty and four had occluded femoropopliteal grafts. Thirty-seven legs of 34 patients were treated with an average of 60 J (range 10–235 J) with successful recanalization in 27 and immediate reocclusion in seven. The 20 successful recanalizations have been followed up for up to 24 months (median 7 months) with only one late occlusion at 5 months. Failed recanalization was due to poor transmission by the delivery device in the early part of the series (five cases), repeated passage of the device down a collateral branch (four cases), dissection at the site of previous surgery (two cases) or no apparent reason (two cases). Immediate reocclusion was due to very poor run off in patients with severely ischaemic limbs (three cases) or technical difficulties with balloon dilatation (two cases). Complete symptomatic relief was obtained in all the cases of radiologically successful laser angioplasty. Early surgery was required in one case following reocclusion of the artery when an angioplasty balloon failed to deflate, and one patient suffered a skin reaction thought to be due to inadequate removal of the sterilizing solution. A different sterilizing procedure is now followed. Laser angioplasty can reduce the number of patients requiring bypass surgery and improvements in the device and access methods may reduce the number of untreatable cases.

The development of laser and fibreoptic technology has made it possible to deliver intense energy, in the form of light, through narrow flexible fibres. This enables the surgeon to unblock occluded arteries by delivering laser energy percutaneously through a narrow fibre. Early work using a bare fibre, although successful, produced an unacceptable rate of vessel perforation[1], so that methods of modifying the delivery device have been sought. The first device to obtain approval for clinical use consisted of a metal probe, heated by energy from a continuous wave laser[2], and this has now been used with some success in the peripheral circulation[3]. However, recent experimental evidence suggests that debris formation may be a problem with such a device[4], which may explain the poor results of the small number of reported cases in which it has been used in the coronary circulation[5].

Theoretical and experimental work has shown that short pulses of laser energy, delivered directly to tissue, result in the ablation of tissue with little surrounding thermal damage[6,7]. Optical devices are now available which can delivery such pulsed energy into a blocked artery without becoming hot and attracting the clot and debris which develop on the metal probe[8,9].

The results and initial follow-up are reported for the first clinical series in which a pulsed laser has been used, via a percutaneous approach, to recanalize occlusion of the superficial femoral artery.

Patients and methods

A total of 40 laser procedures have been performed on 37 legs of 34 patients with severe symptoms of peripheral vascular disease due to complete occlusion of the superficial femoral artery. Initially, laser treatment was only considered for patients with threatened limb loss in whom all other possible treatment options had been attempted or were considered inappropriate. After the first 12 procedures, the indications were relaxed to include any patient who had a clinical indication for vascular surgery with a lesion amenable to laser treatment. All patients with femoropopliteal disease were considered unless: (1) there was evidence of recent sudden deterioration in condition suggestive of an acute occlusion, or (2) adequate access to the superficial femoral artery could not be achieved.

Twenty-six men and eight women with a median age of 69 years (range 37–87) were treated, the right leg being treated in 17 and the left leg in 20 cases; 12 were treated for severe claudication, 14 for rest pain and eight for ulceration or gangrene. Four patients had undergone

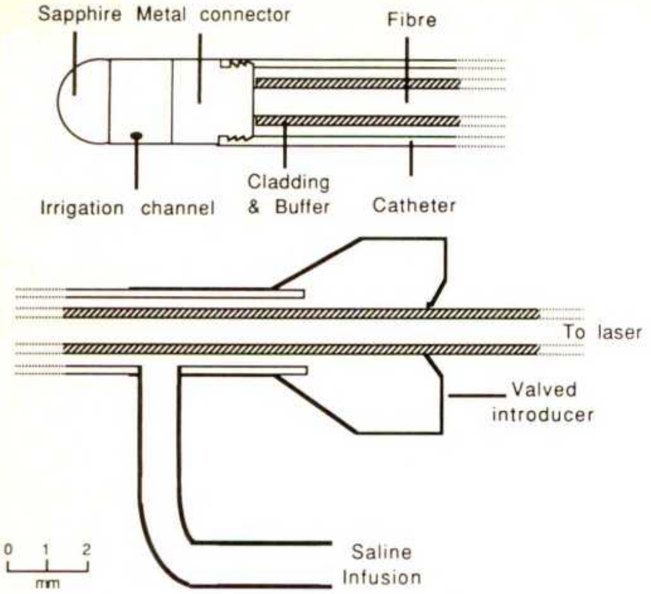

Figure 1 *Diagram of the catheter with an artificial sapphire tip as used for clinical laser angioplasty*

previous femoropopliteal bypass and ten had previous failed attempts at balloon angioplasty on the treated leg. The median (range) ankle:brachial pressure index (ABPI) was 0·6 (0·3–0·7) at rest and 0·2 (0–0·5) after exercise in the claudicants and 0·3 (0–0·7) at rest in those with rest pain or gangrene. All had total occlusion of the superficial femoral artery with a median length of 15 cm (range 2–35 cm); seven had a superficial femoral stump of less than 2 cm, and in three of these there was no stump visible on angiography. Poor run off was not considered a contraindication to treatment; there was an average of two run-off vessels, with three of the treated patients having an isolated popliteal segment. Two patients had evidence of ipsilateral iliac stenosis and these were treated by balloon dilatation before considering laser angioplasty.

There was a high incidence of coexisting disease, such as coronary heart disease, cerebrovascular disease and diabetes mellitus, and most patients were considered a poor risk for general anaesthesia.

Laser angioplasty was carried out with a pulsed NdYAG laser (Lumonics Ltd., Rugby, UK) delivering light in the near infrared at a wavelength of 1064 nm. Pulses of 100 μs duration at a repetition rate of 10 Hz are delivered through a 600-μm core diameter optical fibre with a 2·2-mm diameter hemispherical tip made of sapphire (Surgical Laser Technologies (UK) Ltd., Keighley, UK). The sapphire is mounted on a catheter using a metal connector with a side hole through which normal saline is infused (*Figure 1*). The system delivers between 250 and 350 mJ per pulse, giving an average power at 10 Hz of 2·5–3·5 W. The power output was measured at the beginning of each procedure and the timer set to deliver a series of pulses totalling 5 J (i.e. 1·4–2·0 s).

All lesions were approached through an antegrade puncture of the ipsilateral common or superficial femoral artery under local anaesthesia. A 7 or 8 Fr valved introducer sheath was placed in the superficial femoral vessel and preliminary angiography performed. The site of the upper and lower ends of the occlusion were marked and heparin (5000–10 000 units) was given through the sheath. Saline was infused through the angioplasty device at a pressure of 300 mmHg and rate of 4 ml/min. The device was introduced to the upper end of the occlusion under radiological control, advanced gently until resistance was met and exposures of 5 J were repeated until the occlusion was crossed. The laser fibre was replaced with a guidewire, a catheter was introduced through the occlusion and contrast was injected to demonstrate the integrity of the distal vessels. Balloon angioplasty was then performed working from the distal end of the reopened segment of artery with two inflations to 8 atm (811 kPa), at each overlapping site (*Figure 2*).

Completion angiography was performed and haemostasis secured at the groin puncture site. After 24 h bed rest the patient was mobilized and discharged from hospital on aspirin and dipyridamole. Progress was assessed by symptoms, clinical examination, and by the measurement of ABPI before the procedure and during the follow-up period. Angiography was not repeated routinely but was performed if there was clinical indication.

Results

Of the 40 attempted procedures on 37 legs there was successful recanalization of the superficial femoral vessel in 27. Three repeat procedures were carried out after failures due to device problems and two of these were unsuccessful on the second attempt. None of those patients in whom there was a failure of recanalization suffered from any deterioration in the clinical or radiological severity of their disease and most of those in whom surgery was feasible went on to have the vascular surgery that was originally planned. The reasons for failure of recanalization were evident in most cases. In five there was found to be poor output from the laser device: two were related to fibre damage and three were carried out with a sapphire of different geometry that was found to transmit less energy and produce more heat than the usual sapphire. Four failed recanalizations were due to an inability to reach the site of occlusion because of repeated passage of the device down a side-branch at the upper end of the blockage. Two were due to dissection at the site of anastomosis of a previous suprageniculate bypass graft and two others failed for no apparent reason.

An average of 60 J (range 10–235 J) was required for recanalization and the procedure was tolerated well. Pain

during laser exposure occurred in a few cases and was not severe but was sometimes associated with vessel dissection and was therefore taken as an indication to stop laser exposure and repeat the angiogram.

Of the 27 recanalized vessels, balloon dilatation was performed in 26, the exception being a case in which the guidewire repeatedly passed down a collateral vessel rather than through the channel made by the laser. Despite the lack of balloon dilatation the symptoms improved and the vessel remains patent at 17 months.

In seven cases the vessel reoccluded at the end of the procedure. Three of these were from the first six patients treated and all had gangrene of the extremity with very poor distal run off and little flow through the reopened vessel. In one case the angioplasty balloon broke and the vessel reoccluded while it was being changed, and in another the angioplasty balloon failed to deflate and had to be punctured percutaneously with a needle. In this patient the vessel reoccluded during the procedure and successful, urgent surgery was performed the following day owing to deterioration of symptoms.

Of the patients in whom successful recanalization of the superficial femoral vessel was achieved at 24 h, 20 have now been followed for a period of up to 24 months (median 7 months). Median ABPI showed an increase from 0·4 to 0·6 at rest (statistically significant: $P<0{\cdot}01$, Wilcoxon signed rank test; *Figure 3*) and from 0·2 to 0·7 following exercise. patient required a below-knee amputation for pre-existing gangrene. The stump healed well and the popliteal pulse has remained palpable. All the other patients had complete relief of symptoms. In one case there was reocclusion of the vessel 5 months after the procedure. This patient had previously suffered from rest pain and had a return of claudication at 50 m but declined further treatment. Five patients have been followed up for more than 1 year and all remain asymptomatic, with clinically patent vessels and no deterioration in ABPI (median t rest 0·8). Patency of recanalized vessels has been demonstratedat the time of angiography for symptoms of the untreated leg in two patients at 5 and 6 months after the laser procedure.

Discussion

The use of laser angioplasty, either as an adjunct to, or instead of, balloon angioplasty has two potential advantages over conventional treatment. The major advantage is that lesions that could only be treated by extensive vascular surgery may now be amenable to a relatively non-invasive form of treatment. The second possible advantage is that, because the occluding material is removed rather than simply displaced, the restenosis rate following laser treatment may be less than that seen with balloon angioplasty alone. To show this would require a prolonged randomized trial of laser *versus* conventional angioplasty, so that good evidence is unlikely to emerge for many years, although the proponents of laser thermal angioplasty are already suggesting that restenosis rates are reduced[10].

In the case of long occlusions, even when mechanical recanalization and balloon angioplasty are possible, the long term patency is poor[11]. In the early part of this trial an attempt was made to recanalize every occlusion by mechanical means before considering the use of the laser. Three occlusions of more than 15 cm were recanalized and balloon dilated, but all had reoccluded within 48 h. This trial of mechanical recanalization was therefore dropped from the protocol and only attempted if thought to be indicated by the angiographic appearance.

Because the indications for treatment and severity of disease have great bearing on the results of all forms of treatment for peripheral vascular disease[12], it is important to define the patient group accurately before comparing the results of different treatments. Laser angioplasty may be used as an alternative to balloon angioplasty for a symptomatic stenosis or short occlusion. It may also be used in lesions that are unsuitable for balloon angioplasty. Because it is less invasive than surgery it may be used in patients whose symptoms would not normally warrant intervention, or it may be an alternative to surgery in those for whom this would be the conventional choice of treatment.

In the present series the indications have been limited to this last group. The majority of patients had rest pain, ulceration or gangrene, and all had long occlusions of the superficial femoral artery which were unsuitable for balloon angioplasty. The only two patients whose occlusions were less than 5 cm in length had already undergone failed attempts at conventional balloon angioplasty. This must be taken into account when results are compared with those reported by others. For example, in the large series recently reported with the heated probe[10], two-thirds of patients were claudicants, in only a quarter was there an occlusion over 7 cm in length and over 20 per cent had a stenosis rather than an occlusion. Other groups are treating an even higher proportion of stenoses[13].

The patients who have had a successful clinical result in this series have all been saved an operation by a relatively minor procedure with few complications. Only one patient deteriorated after the procedure and this was one in whom laser recanalization was successful but the angioplasty balloon failed to deflate and the vessel reoccluded. There was no evidence that an attempt at laser angioplasty adversely affected the chances of subsequent successful surgery in any of the patients having an unsuccessful laser procedure.

Most of the unsatisfactory results were associated with problems which may well be resolved with improved devices and techniques. The major problem is failure of access, either because the device passed down a side-branch and could not be induced to go down the main channel, or because of disease or scarring in the groin. The present device is not sufficiently flexible to be passed from the brachial or contralateral femoral arteries. These problems are likely to be overcome by new devices which are at present being evaluated[9] or by using the laser in the operating theatre via a surgical exposure of the vessel. The problems relating to failure of output or sterilization of the fibre are also likely to be resolved by the development of a sterile, prepacked, disposable device. The present device is reused, mainly because of the high cost of sapphires.

Although only five patients have so far been followed up for more than a year, the initial results are promising. There has only been one late occlusion in the 20 patients followed for up to 24 months. If this trend continues then it is likely that a substantial number of patients could avoid the need for major surgery, as the life expectancy of this group of patients is known to be poor[14].

Several possible combinations of laser and device are currently under investigation for the purpose of laser angioplasty[15]. Although a sapphire device is being used elsewhere for laser angioplasty[16], this has been used with a continuous wave laser which does not have many of the theoretical advantages of direct delivery of light to the tissue. Experimental work shows that use of a pulsed laser with a transparent device can produce ablation with the minimum of surrounding damage and debris formation[9].

The current series shows that the combination of pulsed laser and transparent device is now a feasible clinical method for treatment of occlusions in the peripheral vessels and it seems likely that laser angioplasty will become a useful addition to the options for the treatment of peripheral vascular disease. If the early safety record is maintained, it may become justifiable to treat an increasing number of patients with less severe, but disabling symptoms, in whom the risks of surgery are not warranted.

Once experience has been gathered in the peripheral circulation, the extension of the technique to the coronary vessels has potential advantages over presently available methods.

Operative measurements using a newly developed Doppler flowmeter were made on 47 in situ *femorodistal bypass grafts performed for critical ischaemia. Graft blood flow, peripheral resistance and impedance were measured before and after the injection of 15 mg papaverine down the graft. The proportion of retrograde blood flow at the distal anastomosis was also measured. The success of a graft at 1 month was defined by patency on duplex ultrasound scanning, a rise in the Doppler ankle pressures and an improvement in the clinical state of the limb. By these criteria the 1-month primary success rate was 35 out of 47 (74 per cent). Graft blood flow was of little value in predicting graft outcome but, combined with segmental pressures, accurately located six of eight technical problems which were successfully corrected. After papaverine, the peripheral resistance of all the successful grafts fell below one peripheral resistance unit (PRU). No single measurement was able to completely distinguish between success and failure, although discriminant analysis of all measurements was able to predict success with a sensitivity of 100 per cent and specificity of 97 per cent. A simpler combination of a peripheral resistance after papaverine <1 PRU and a retrograde blood flow <33 per cent predicted success, with a sensitivity of 97 per cent and specificity 83 per cent. These criteria have been validated on a further 26 grafts, achieving a sensitivity of 88 per cent and a specificity of 75 per cent. Simple operative measurements, using a newly developed Doppler flowmeter, enable the detection of technical problems and the accurate prediction of the early outcome of femorodistal grafting.*

Keywords: Doppler ultrasound, blood flow, femorodistal bypass

Despite recent advances, such as the *in situ* technique, up to one-third of all femorodistal bypass grafts performed for critical ischaemia occlude within the first year, the majority within the first month[1]. A retrospective study of 85 *in situ* vein grafts performed at the Bristol Royal Infirmary found that the 1-month occlusion rate was 20 per cent, despite the peroperative use of a pulse volume recorder[2]. Early failure may lead to a higher level of amputation[3], a lengthy hospital stay and wasted operating time.

It has been known for over 20 years that graft patency is dependent on blood flow[4] but many vascular surgeons are still hampered by a lack of haemodynamic information during reconstruction. Electromagnetic flowmeters are expensive and can be difficult to use in theatre[5], and completion arteriography provides little information about the functional capacity of the run off[6]. Indirect methods such as Doppler ankle pressures[7], plethysmography[8] and transcutaneous oxygen tension[9] are generally easy to use and relatively inexpensive. However, there may be a significant delay before a positive result is recorded in a successful graft and a negative result does not indicate the cause of the problem.

The object of this study was to evaluate the use of a newly developed Doppler flowmeter[10] during femorodistal reconstruction to detect technical problems and to see whether the early outcome could be predicted.

Patients and methods

Forty-seven consecutive *in situ* vein femorodistal bypass grafts performed for critical ischaemia[11] were studied prospectively. There were 25 men and 18 women aged between 42 and 87 years (median 71 years); four patients received bilateral grafts. Thirty-three operations were performed for tissue loss, the other 14 for persistent rest pain; 12 patients were diabetic. Preoperative assessment was based on a combination of clinical examination, transfemoral arteriography and Doppler ankle pressures.

The 'non-reversed' technique of *in situ* vein bypass was used in all cases[2]. The vein was completely exposed and mobilized to avoid the risk of arteriovenous fistulae. Valve disruption was performed from the distal end using a Hall valvulotome once the vein was distended with blood from the completed proximal anastomosis[12]. The proximal anastomosis was to the common femoral artery in 44 cases and to the lower end of a previous aortofemoral graft in three. The distal anastomosis was to the popliteal artery below the knee in 28 cases, the tibioperoneal trunk in ten and a single calf vessel in nine. Five preoperative transluminal angioplasties and three endarterectomies were performed to improve the iliac artery inflow.

The Doppler flowmeter is based on a 10 MHz pencil probe and a mean frequency estimator whose output is proportional to the mean blood velocity[10]. The errors associated with measurement of the vessel diameter and angle of insonation[13] are minimized by clipping a plastic cuff snugly around the vessel which fixes the probe angle at 50°. A range of cuffs from 3 to 14 mm have been constructed, as well as a compression gauge which is used to measure the vessel wall thickness and hence the vessel internal diameter (*Figure 1*). The probe, cuffs and gauge are all sterilized by activated glutaraldehyde. Blood flow is calculated by the flowmeter from the mean blood velocity and the vessel internal diameter using an experimentally determined calibration factor to compensate for uneven insonation of the vessel lumen. Unlike electromagnetic instruments, the Doppler flowmeter is easy to use because no zeroing is required and, provided a signal is obtainable, its sensitivity is unaffected by the vessel wall composition. Because it does not depend on electrical contact with the vessel, flow can be measured in non-conductive materials including thin-walled polyvinylchloride shunts and polytetrafluoroethylene grafts, provided that they are wetted well to remove any air bubbles in the wall.

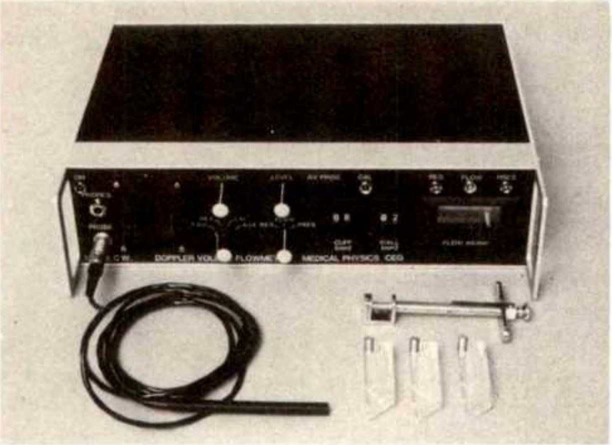

Figure 1 *The Doppler flowmeter together with the 10 MHz pencil probe, a range of acrylic cuffs and the compression gauge*

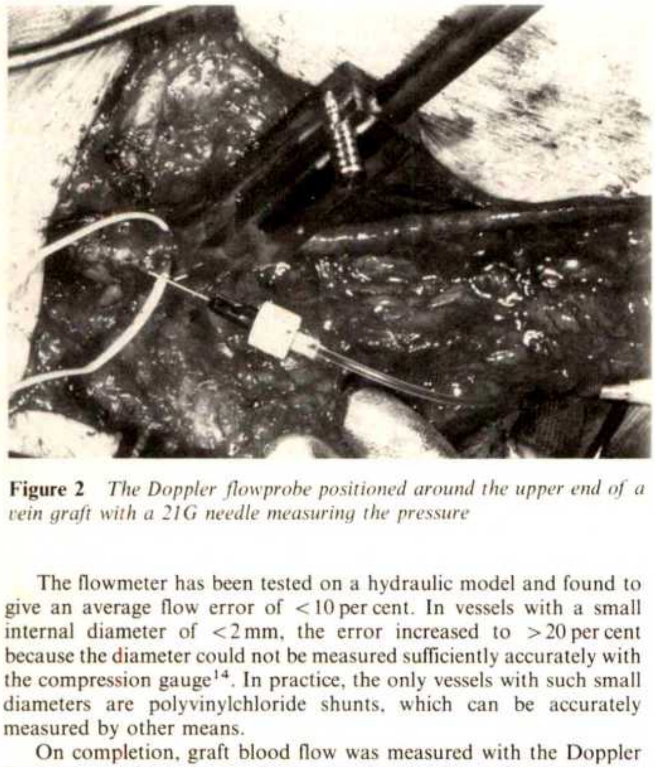

Figure 2 *The Doppler flowprobe positioned around the upper end of a vein graft with a 21G needle measuring the pressure*

The flowmeter has been tested on a hydraulic model and found to give an average flow error of <10 per cent. In vessels with a small internal diameter of <2 mm, the error increased to >20 per cent because the diameter could not be measured sufficiently accurately with the compression gauge[14]. In practice, the only vessels with such small diameters are polyvinylchloride shunts, which can be accurately measured by other means.

On completion, graft blood flow was measured with the Doppler flowprobe positioned near the proximal end. The graft pressure was also measured with a Gould P231D® (Gould Incorporated, Oxnard, California, USA) pressure transducer connected to a 10-cm length of manometer tubing and a 21G (green) needle inserted into the graft (*Figure 2*). After measuring the total graft flow, the popliteal artery proximal to the distal anastomosis was occluded to prevent retrograde flow and the distal flow was measured. The amount of retrograde flow was then expressed as a percentage of the total, where

$$\text{Retrograde flow} = \frac{\text{Total flow} - \text{Distal flow}}{\text{Total flow}}$$

The peripheral resistance was then calculated from the mean distal graft blood pressure and flow and expressed in peripheral resistance units (PRU), where 1 PRU = 1 mmHg ml^{-1} min^{-1}. The mean systemic blood pressure was also recorded from a cannula inserted into the radial artery. This allowed calculation of the proximal inflow resistance of the iliac artery, where

$$\text{Proximal resistance} = \frac{\text{Systemic pressure} - \text{Graft pressure}}{\text{Graft flow}}$$

The peripheral resistance was then measured again after the injection of 15 mg papaverine down the graft. The peripheral resistance was measured when graft flow was maximal, which was usually within 1 min; flow returned to baseline within 3 min. If the peripheral resistance failed to fall after papaverine then the pressures at the distal end of the graft and in the artery below the anastomosis were measured. If there was a pressure drop >10 mmHg, a valvulotome was repassed to exclude persistent valve cusps, or the distal anastomosis was revised. An arteriogram was obtained if the problem was more distal and an embolectomy was performed if indicated.

During measurement of the peripheral resistance, the pressure and flow waveforms were also stored digitally on an Apple 2E® (Apple Computer Company, Cupertino, California, USA) microcomputer. The input impedance curve was subsequently calculated by Fourier transformation analysis and the area under the curve up to 40 rad was measured. Measurement of the input impedance is theoretically superior to resistance as it also looks at the frequency dependent elements of the arterial system[15].

The success of a graft at 1 month was defined by patency on duplex ultrasound scanning, a rise in the postoperative Doppler ankle: brachial pressure index of >0·25[16] and a clinical improvement in the limb. Statistical analysis was by the Mann–Whitney *U* test with analysis of variance for each parameter and by discriminant analysis of all the parameters combined.

Results

According to the above criteria, 35 grafts were successful at 1 month (primary success rate 74 per cent). Of the 12 failed grafts, eight occluded between 12 h and 19 days postoperatively, and four grafts, although patent, resulted in no improvement clinically or in the Doppler ankle pressures. Of the 12 failures, eight were revised, four successfully.

The results of all the measurements are summarized in *Table 1*. Although there was a significant difference between the total blood flow of successful and failed grafts ($P = 0·02$), it was of little value in predicting graft outcome. Measurement of flow combined with segmental pressures accurately located six of eight technical problems, which were successfully corrected. These included two persistent valve cusps, one anastomotic stenosis, one kinked graft and two distal thromboemboli. The two missed problems were a graft that kinked on extension of the knee following skin closure and an intimal dissection at a distal anastomosis. Both caused occlusion within 24 h but these were two of the grafts that were successfully revised. The other two successful revisions received distal extensions to bypass disease at the origins of the tibial vessels.

There was a statistically significant difference in the graft flow distally between the successful and failed grafts ($P = 0·002$) although there was still a considerable overlap between success and failure, one successful graft having a flow of only 24 ml min^{-1}. The proportion of retrograde flow at the distal anastomosis was not significantly different by itself ($P = 0·18$), although the proportion in five failed grafts was >33 per cent. The proximal resistance of the iliac artery was also not significantly different in successful and failed grafts ($P = 0·13$). Although two failures had high resistances of around 0·4 PRU, they both had other potential reasons for failure.

The peripheral resistance before papaverine was of similar significance to the distal flow (*Figure 3a*; $P = 0·002$) but was

Table 1 *Results of measurements on 47 femorodistal* in situ *vein grafts*

Measurement	Success	Failure	*P*
Proximal resistance (PRU)	0·05 (0–0·27)	0·08 (0–0·43)	0·13
Total flow (ml min^{-1})	96 (34–196)	61 (15–123)	0·02

highly significantly different in successful and failed grafts after papaverine (*Figure 3b*; $P = 0{\cdot}0001$). After papaverine the peripheral resistance of all the successful grafts fell below 1 PRU, whereas the failures tended to remain high. Four failed grafts with borderline peripheral resistances had a retrograde flow >33 per cent. These were the four grafts that, although patent at 1 month, resulted in no clinical or Doppler improvement. Arteriograms were obtained for all grafts with a poor response to papaverine once a more proximal technical problem had been excluded. These all showed severe distal disease except for the two cases where thromboemboli were successfully removed.

The input impedance before papaverine was not significantly different ($P = 0{\cdot}15$) but this was not the case after papaverine ($P = 0{\cdot}004$). Following papaverine the impedance curves of the successful grafts flattened out, becoming predominantly resistive.

Although no single measurement was able to completely distinguish between success and failure, discriminant analysis of all parameters achieved a correct classification of all of the 35 successes and 11 of the 12 failures (sensitivity 100 per cent, specificity 97 per cent). A much simpler combination of peripheral resistance after papaverine <1 PRU and a retrograde flow <33 per cent achieved a sensitivity of 97 per cent and a specificity of 83 per cent. The only failures not correctly classified were the two missed technical problems.

These criteria have now been validated on a further series of 26 consecutive femorodistal grafts. Four technical problems were detected and corrected. Successful graft outcome at 1 month was predicted in 16 of 18 cases, with a sensitivity of 88 per cent and a specificity of 75 per cent. This series included four very distal grafts to tibial vessels near the ankle. These tended to have a lesser response to papaverine and a higher proportion of retrograde flow without compromising distal perfusion.

Discussion

The Doppler flowmeter is now used routinely during all types of arterial reconstructive surgery, including femorofemoral and femorodistal bypass and carotid endarterectomy. It has proved easy to use in the operating theatre without technical support. No electrical contact with the vessel or zeroing is required and there is no change in sensitivity with different graft materials. Although initial calibration of the system is required, regular calibration of individual probes is unnecessary. The need for only one transducer also reduces costs.

It should be no surprise that measurement of resistance was better than that of flow alone. Graft blood flow is dependent on many factors, apart from the run off, including the systemic blood pressure and the tone of the capillary bed, both of which may also be dependent on the anaesthetic[17]. Measurement of the peripheral resistance avoids errors due to poor graft perfusion and the administration of papaverine reduces errors due to variable capillary tone[18]. Graft blood flow in the early postoperative period increases as the capillary bed opens up[19] and this may explain why measurement of resting flow or peripheral resistance before papaverine are less good at predicting outcome.

Interestingly, a resting blood flow of 120 ml min^{-1} was recorded in a vein graft with a minimum diameter of only 2 mm. This suggests that, even for small calibre grafts, blood flow is limited more by the peripheral resistance than by the diameter. Although both the grafts with a high proximal iliac resistance had other potential reasons for failure, it seems likely that it was a contributing factor. Although more moderate iliac disease may not cause femorodistal graft failure[20], it may limit its maximum potential. Correction by transluminal angioplasty, endarterectomy or grafting seems advisable if full clinical benefit is to be obtained.

A high retrograde flow of blood at the distal anastomosis was usually found in combination with a high peripheral resistance due to distal disease, resulting in retrograde flow up a patent proximal popliteal artery. This situation is analogous to the formation of an arteriovenous fistula at the distal anastomosis, or leaving a venous tributary intact. Blood may be shunted away from the distal circulation even though graft patency is maintained[21]. All four grafts that remained patent without any clinical or Doppler improvement had retrograde flows >33 per cent. A high retrograde flow suggests that the distal anastomosis may require revision to a more distal level. For very distal grafts near the ankle, a high retrograde flow may not impair distal perfusion and probably helps to maintain patency. These grafts also have a lesser response to papaverine, perhaps because of the smaller volume of muscle perfused.

The use of input impedance to predict graft function was disappointing, despite its theoretical advantages. Most of the differences between success and failure were in the resistive elements which were more simply assessed by measurement of the peripheral resistance.

In conclusion, simple operative measurements during femorodistal bypass, using a newly developed Doppler flowmeter, enable most technical problems to be detected and early graft outcome to be accurately predicted. This should lower the incidence of early graft failure, with a consequent reduction in patient morbidity, hospital stay and wasted operating time.

Saphenous vein in infrainguinal bypass

S. Karacagil, O. Nybacka and B. Almgren

Department of Surgery, University Hospital,
Uppsala, S-751 85, Sweden
Correspondence to: Dr S. Karacagil

It is generally accepted that autogenous saphenous vein is the best graft material for bypass procedures below the inguinal ligament. When a satisfactory single length of saphenous vein is not available for reversed, *in situ* or non-reversed translocated techniques, totally autogenous composite grafts consisting of different combinations of greater and lesser saphenous vein and/or arm veins have been advocated to obtain an adequate length to revascularize ischaemic limbs[1,2]. More recently a new graft has been reported using arm veins to give a combination of reversed cephalic and non-reversed basilic vein in continuity that is long enough for distal reconstructions[3].

We have used an analogous technique in two patients with double greater saphenous vein trunks, each of which had insufficient length on its own to complete a femoropopliteal below-knee bypass. Both branches of the saphenous vein were mobilized for as far as their diameters were adequate. The trunk with the larger diameter was reversed and used as the proximal part of the graft, the distal part consisting of the smaller non-reversed trunk. The valves in the non-reversed segment were destroyed with a valvulotome introduced from the distal end of the graft. The excised bifurcation area was sutured (*Figure 1*).

This technique avoids the need for an additional venovenous anastomosis to obtain the requisite graft length in cases with a double greater saphenous vein where each trunk is not on its own long enough to complete the bypass procedure.

Dr S. N. Vasdekis

Surgery of the short saphenous vein is associated with a high recurrence rate because of variations in the anatomy or inadequate clinical examination. To prevent this, accurate definition of the pattern and level of termination of the saphenopopliteal junction and flush ligation is necessary. Clinical examination, Doppler ultrasound, duplex scanning and peroperative venography have been compared to assess the level of termination of the short saphenous vein. In all, 64 limbs of 46 patients were examined. In 39 limbs there was primary short saphenous incompetence, in 13 limbs there was recurrent short saphenous incompetence; in ten of these there was incompetence of the gastrocnemius vein. In 12 limbs a duplex scan did not demonstrate incompetence of the short saphenous vein or gastrocnemius vein. The accuracy of these methods when locating incompetence of the short saphenous vein to within 2 cm of the saphenopopliteal junction was 56 per cent for clinical examination, 64 per cent for Doppler ultrasound and 96 per cent for duplex scanning. When there was no saphenopopliteal junction (9 per cent), duplex scanning correctly detected the pattern of the incompetent vein. The apparent success of clinical examination was because the vein was not felt above the femoral intercondylar groove and 52 per cent of the veins terminated at this level. Duplex scanning is a non-invasive technique which is almost as accurate as venography and provides additional haemodynamic information about the incompetent veins by demonstrating the presence and extent of reflux.

Keywords: Short saphenous vein, Doppler ultrasound, duplex scanning, peroperative venography

Surgery of the short saphenous vein is a common surgical procedure, associated with a high recurrence rate[1]. This is due to variations of the anatomy which are not always detected before operation, with the result that flush saphenopopliteal ligation is not always achieved.

The usual methods of assessing the short saphenous system are clinical examination and the use of Doppler ultrasound. These, together with venography[2–4], which remains the gold standard, are able to demonstrate the presence of reflux and detect the level of the saphenopopliteal junction.

Recently, duplex scanning was introduced[5] in the study of venous disease with promising results. It has been shown to be very accurate in the detection of venous thrombosis[6,7] and deep vein insufficiency[8].

The aim of this study was to compare clinical examination, Doppler ultrasound and duplex scanning with peroperative venography for the detection of the level and pattern of termination of the short saphenous vein.

Patients and methods

The short saphenous vein termination was examined in the vascular laboratory before operation in 46 patients (64 limbs). There were 17 men (mean age 45·2 years) and 29 women (mean age 47·9 years). Primary short saphenous vein insufficiency was found in 39 limbs (61 per cent) and recurrent insufficiency in 13 (20 per cent). In 12 limbs the short saphenous vein was found to be competent but these were included in the study because, although the distal short saphenous vein was involved, there was incompetence due either to a communication from the long saphenous vein or to the midcalf perforating vein. In these cases only duplex scanning could be compared with venography.

Clinical examination was performed with the patient standing and the knee flexed so that the fascia over the popliteal fossa was relaxed. The short saphenous vein was palpated and followed proximally until it could no longer be felt. This was assumed to be the level of its junction with the deep system and was marked on the skin.

Doppler ultrasound examination was then performed. A pocket CW directional Doppler flowmeter with an 8 MHz probe was used (Sonicaid® BV102, Oxford Sonicaid Ltd., Chichester, UK). The patient was standing, facing away from the examiner and holding on to a frame or table. The knee on the side to be examined was flexed so that the popliteal fascia was relaxed. The Doppler probe was positioned on the skin over the popliteal fossa at an angle of approximately 45° so that the signals from the popliteal artery and popliteal vein were audible. The calf was then manually compressed and venous flow towards the heart was detected. On release of compression, if insufficiency was present, a retrograde venous flow was detected. This indicated reflux into either the short saphenous vein or the popliteal vein. When reflux was heard the calf compression was repeated but now with compression of the short saphenous vein by an assistant distal to the probe. If reflux persisted despite digital compression of the short saphenous vein, it was inferred that the reflux is located in the popliteal vein. If abolished, the reflux was considered to be in the short saphenous vein[9]. After the reflux in a proximal direction, the site of termination of the short saphenous was determined to be the highest level of the detection of reflux. This level was marked on the skin.

Duplex examination was performed using a 7·5 or 10 MHz imaging crystal coupled with a 3·0 MHz pulsed Doppler crystal (Diasonics® DRF300, Diasonics–Sonotron, Bedford, UK). The patient was examined as for the Doppler study. The probe was positioned over the skin of the popliteal fossa longitudinally and adjusted so that three structures were identified: the pulsating popliteal artery lying deepest, the popliteal vein lying more superficial and parallel to it and, even more superficial, the short saphenous vein (*Figure 1*). Because of anatomical variations, careful scanning was performed above and below the popliteal fossa to identify all the vascular structures. The gastrocnemius veins were easily recognized by their deep course between the popliteal vein and short saphenous vein and by their emergence from the gastrocnemius muscle. They often communicated distally with the midcalf perforating vein. Another common vein of the area was the Giacomini vein

(femoropopliteal vein) that ascends from the proximal part of the short saphenous vein deep in the posterior aspect of the thigh, parallel to the skin, to terminate as the posteromedial tributary of the long saphenous vein or rarely by joining tributaries of the internal iliac veins. The flow in these veins was assessed by focusing the pulsed Doppler scanner in the lumen and manually compressing the calf. On sudden release, if there was incompetence, retrograde flow was detected and the grey scale spectrum was recorded. Thus, all incompetent sites were recorded. By following the course of the incompetent vein proximally using continuous imaging, the level of the junction with the deep system was detected and marked on the skin. If more than one vein was incompetent, e.g. the short saphenous and gastrocnemius veins, each site was marked.

At operation the patient was placed in a lateral position and a peroperative venogram, previously described[10], was performed. Hexabrix® (May and Baker Ltd., Dagenham, UK) or Niopam® 300 (E. Merck Ltd., Alton, UK) was used as the contrast and usually 20 ml were enough to visualize the anatomy. Needles of different sizes were placed at the sites of skin marked and used as markers for comparison on the venogram (*Figure 2*). After on-table venography the operation was performed with the patient in the lateral position using a small skin incision. The operative findings confirmed the accuracy of the various techniques (*Figure 3*).

Results

The level of the saphenopopliteal junction is shown in *Figure 4*. In 56 per cent the termination was within 2–5 cm of the knee joint. This was also the level of the femoral condyle and usually the short saphenous vein could not be palpated above this level, giving the impression that the clinical assessment was accurate. In 27 per cent the short saphenous vein terminated more than 5 cm above the knee joint and in six cases (9 per cent) joined the long saphenous vein. In one leg the proximal part of the short saphenous vein was absent, the distal part connecting to the gastrocnemius vein via a midcalf perforator. In this limb the termination of the gastrocnemius vein was determined and found to be 1 cm above the knee joint. Duplex scanning detected the presence of an incompetent gastrocnemius vein in ten legs (16 per cent), of which seven were in association with primary short saphenous insufficiency and three were the cause of recurrence after previous short saphenous ligation and stripping. There were also five examples of saphenopopliteal incompetence via the Giacomini vein detected by duplex scanning. In all legs venography accurately (100 per cent) located the level of the junction as confirmed by the intraoperative findings.

The results of each method are presented as percentages measured to detect the level of the junction in *Table 1*. We accept the distance of ±2 cm from the junction as the maximum distance needed to perform an accurate flush ligation. Venography always demonstrates the junction, while duplex scans have an accuracy of 96 per cent, compared with 56 per cent by clinical examination and 64 per cent by Doppler. In 9 per cent

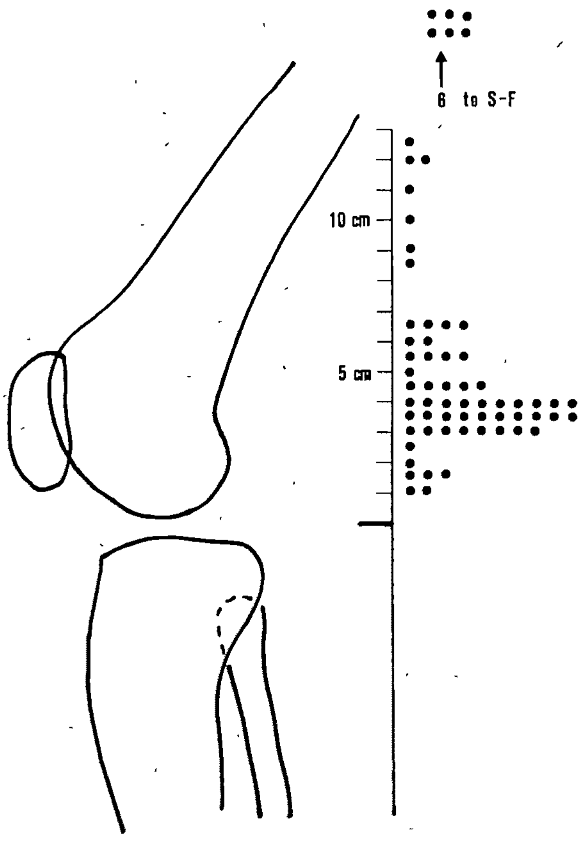

Figure 4 *Level of termination of the short saphenous vein as shown by venography (centimetres above knee joint). In six cases the short saphenous vein joined the long saphenous vein (S-F), in one leg the short saphenous vein (SSV) was absent*

of legs where there was no junction, duplex examination correctly visualized the anatomy.

The 100 per cent accuracy of venography was achieved with only one film in the majority of examinations. In nine limbs a second and in three limbs a third film was required to demonstrate the termination pattern. In the limbs in which duplex was unable accurately to locate the junction it was because the vein continued deep in the thigh or there was an anterior termination of the short saphenous vein in the popliteal vein, resulting in poor image resolution. The average time of examination needed for duplex scanning was 5 min.

Table 1 *Accuracy of the four techniques in detecting the level of termination of the short saphenous vein*

	Accuracy (%)		
	At the junction	At ±1 cm	At ±2 cm
X-ray	100	100	100
Clinical	9	31	56
Doppler	8	21	64
Duplex	29	50	96*

Data are measured from the level of the junction. In 9 per cent of limbs where no junction was present duplex examination correctly demonstrated the anatomy, and the overall accuracy of the technique was 96 per cent. * This figure includes the six limbs in which the duplex scan indicated that the short saphenous vein was not connected to the popliteal vein

Discussion

The level of termination of the short saphenous vein is variable[2,3,10–15]. In the majority (60 per cent) there is a distinct saphenopopliteal junction 2–7 cm above the level of the knee joint. In 30 per cent the short saphenous vein joins the deep system in the thigh or continues to the proximal long saphenous vein. In 10 per cent there is a low termination in the calf joining the gastrocnemius vein via the midcalf perforator or the long saphenous vein via a communicating vein. In our series 26 per cent of limbs showed a high termination of the short saphenous vein, which corresponds with previous reports.

Clinical examination appeared to be accurate but was not confirmed by this study. Clinical examination can easily detect a dilated short saphenous vein but provides uncertain information about the termination level or pattern.

Doppler ultrasound was not found to be as accurate as previously claimed[16]. It demonstrated the highest level where reflux was detected, which was not always the level of the saphenopopliteal junction. It could not differentiate between reflux in the popliteal vein and in the gastrocnemius or Giacomini veins. This may explain the 5 per cent error found when Doppler alone was used for the detection of popliteal reflux[9]. Doppler examination can accurately detect the presence of reflux in the area[17] but, in our experience, it did not always locate the level and pattern of the saphenopopliteal junction.

Peroperative venography provided 100 per cent accuracy on the level and pattern of termination of the short saphenous vein. If there was any doubt the venogram was immediately repeated, sometimes using a different injection site. However, although providing accurate anatomical information, this method did not demonstrate the presence and site of reflux.

Duplex scanning, a non-invasive technique, is almost as accurate in determining the level of the saphenopopliteal junction as venography It can also demonstrate the presence of reflux in individual veins. It is possible for the first time using a non-invasive technique to demonstrate the presence of reflux at the short saphenous vein termination. Duplex scanning can also diagnose and demonstrate incompetence of the gastrocnemius vein[18]. The few cases in which duplex scanning was not accurate were a result of unusual anatomy and of the resolution of the machine. In the near future, with new-generation machines, the higher imaging resolution and penetration may achieve an almost 100 per cent accuracy for duplex scanning. The technique has the advantage that it is non-invasive, takes about 5 min, and is easily repeated. The disadvantage is that such machines are not available in every district hospital and experience is required for its use. When it is not available, venography remains a reliable method of visualizing the anatomy of the veins in the popliteal fossa.

It is concluded that duplex scanning, when available for arterial studies, should also be used for the assessment of the short saphenous vein. This, in combination with venography, will reduce the high recurrence rate seen after short saphenous vein surgery by obtaining accurate assessment of the anatomical and haemodynamic variations in the area.

Randomized study of adjusted versus fixed low dose heparin prophylaxis of deep vein thrombosis in hip surgery

D. A. Taberner, L. Poller, J. M. Thomson, G. Lemon* and F. J. Weighill*

*UK Reference Laboratory for Anticoagulant Reagents and Control and *Department of Orthopaedic Surgery, Withington Hospital, Manchester M20 8LR, UK*

Correspondence to: Dr L. Poller

A randomized study of adjusted versus *fixed low dose heparin prophylaxis has been conducted in 100 patients undergoing surgery for hip replacement or fractured neck of femur. The two types of patients were randomized independently into the adjusted and fixed dose regimens. Patients in the adjusted group were controlled by an activated partial thromboplastin time method particularly responsive to the anticoagulant effect of heparin. The aim was to maintain the peak value just above the upper limit of the normal range. Adjustment of dosage began 24 h after surgery in the replacement group and 24 h after admission in the fracture group. Significant improvement in protection against postoperative deep vein thrombosis, assessed by venography, was observed in the adjusted group undergoing hip replacement* ($P=0.013$) *and overall in both groups* ($P=0.017$) *compared with a conventional fixed dose subcutaneous regimen (calcium heparin 5000 units, 8-hourly). In most instances, adjustment resulted in increased heparin dosage but this was not associated with any evidence of excessive bleeding.*

Keywords: Heparin, deep vein thrombosis, hip surgery

Subcutaneous heparin in fixed low dosage is of limited value in preventing venous thromboembolism in patients undergoing hip surgery[1]. We have previously shown that the anticoagulant effect, whether measured by activated partial thromboplastin time or anti-Xa assay, is variable when this regimen is given to patients undergoing major surgery[2]. Dose adjustment according to clotting response was considered in a further study of the prevention of venous thrombosis. Patients on heparin in whom prophylaxis failed after hip surgery were found to give activated partial thromboplastin times less than the upper limit of normal[3]. Levraz *et al.* subsequently reported that heparin dose adjusted according to the activated partial thromboplastin time response provided better protection after total hip replacement[4], but in their study the adjusted dose group was contrasted with a conservative fixed dose regimen (3500 units 8-hourly). In the present investigation, adjusted dosage of calcium heparin is contrasted with a conventional fixed dose (5000 units 8-hourly) in patients undergoing elective hip replacement or surgery for fractured femur.

Patients and methods

One hundred patients requiring operative treatment of total hip replacement or fractured neck of femur over a 2-year period from July 1985 were admitted to the study after giving informed consent. Exclusions comprised patients with any underlying bleeding tendency, hepatic disease, uncontrolled hypertension, active peptic ulceration, previous history of thromboembolism, cerebrovascular accident, oral anticoagulant treatment, aspirin ingestion during the previous week, allergy to iodide, pathological fracture and malignant disease. Patients were allocated to the adjusted dose regimen or the fixed dose heparin group according to random tables. Those with fractures and undergoing hip replacements were randomized independently

Hip fractures

Heparin (Calciparine®, Sanofi UK, Manchester, UK) 5000 units was administered subcutaneously 8-hourly after admission In the fixed dose regimen, this was continued until the 14th postoperative day if the patient was mobile or until the day of complete mobilization. Patients with hip fractures in the adjusted dose group received 5000 units 8-hourly for the first 24 h. Heparin was then adjusted daily according to the activated partial thromboplastin time result. The target range was 50–55 s. The adjusted dose heparin was injected by calibrated syringes, allowing the dose to be varied by 1250 units.

Hip replacements

Patients were given their first dose of 5000 units heparin with the premedication and subsequently treated with a fixed dose or with adjustment as above

Blood samples for measurements of the activated partial thromboplastin time

Blood was collected daily, 3 h after the morning dose of heparin, using a 19 gauge butterfly needle (discarding the first 2 ml) The specimen was immediately placed in 3·13 per cent trisodium citrate ($Na_3C_6H_5O_7$ $2H_2O$) in plastic containers (nine volumes of blood to one volume of anticoagulant) and kept at 4°C It was transported without delay to the laboratory and processed as previously described, using the Manchester activated partial thromboplastin time reagent[3]

Diagnosis of deep vein thrombosis

[^{125}I]-labelled fibrinogen scanning was performed as previously described[3]. Ultrasound examination of femoral vein flow was undertaken using a Sonicaid BV102® blood flow detector (Sonicaid Ltd, Chichester, UK). These tests were performed daily, excluding Saturdays and Sundays. Impedence plethysmography was carried out at the end of the first and second postoperative weeks Venography was performed to confirm the presence of venous thrombosis if any of the above screening tests were positive

Blood loss

Postoperative blood drainage was measured. The amount of blood transfused and haemoglobin levels were recorded before operation and during the first and second postoperative weeks.

Wound haematoma

A clinical evaluation of wound sites for haematoma was made daily

Comparability of patient groups

The distribution of age, weight, sex and type of surgery was analysed for the two treatment groups

Results

There were 72 patients in the elective hip replacement group, one of whom did not proceed to surgery. These were well matched according to the comparability criteria. There were 28 patients with fractures but these showed minor differences between the fixed dose and adjusted dose groups (*Table 1*).

The presence of deep vein thrombosis was confirmed by venography in nine patients. Eight were in the fixed dose group and one in the adjusted dose group (*Table 2*). The incidence was 2 per cent in the adjusted dose group and 17 per cent in the fixed dose group. This difference was significant ($P=0{\cdot}017$, Fisher's exact test; *Table 3*). When the hip replacements were analysed separately, the incidence of venous thrombosis was lower in the adjusted regimen compared with the fixed regimen ($P=0{\cdot}013$). No positive venograms were found in the adjusted group, compared with six in the fixed dose patients. The numbers of patients with fractures was too small for separate analysis.

Venograms were obtained in 20 of the 31 patients with positive screening tests. In the remaining 11 patients a satisfactory venogram was not obtained. The patients were equally distributed between adjusted and fixed groups (11 per cent in each).

During the postoperative phase before the occurrence of deep vein thrombosis, the activated partial thromboplastin time was less than 50 s, the lower limit of the target range, in five of the six hip replacement patients who developed venographically proved thrombosis. The sixth patient had a satisfactory prolonged clotting test before diagnosis of thrombosis, at which time the test had become accelerated. The six patients were all in the fixed dose group as there were no failures of prophylaxis in the adjusted group with elective replacements.

In the hip fractures, prophylaxis failed in one adjusted dose patient. The activated partial thromboplastin time remained below the lower limit of the normal range and well below the target value in spite of considerable increase of dosage to 11 250 units every 8 h. A therapeutic effect was only observed after confirmation of the deep vein thrombosis. In two hip fracture patients receiving fixed dosage prophylaxis failed. The activated partial thromboplastin time test remained above the target range in one patient, but below the range in the second before the detection of deep vein thrombosis.

In the adjusted group, 62 per cent of activated partial thromboplastin time result were greater than the target value. This compared with 42 per cent in the fixed dose group ($P<0{\cdot}001$, χ^2 test). The distribution of the mean result for the fixed and adjusted dose patients is given in *Figure 1*. The mean heparin dose for the adjusted patients was greater (94·5 units/kg three times a day), than in the fixed dose group (77·1 units/kg three times a day; $P<0{\cdot}001$; see *Figure 2*).

Postoperative bleeding was assessed by measuring postoperative drainage, the number of units of blood transfused, the change in haemoglobin and the incidence of wound haematoma. Analysis was only possible with the hip replacement groups. None of the above indicators of bleeding showed any significant difference between the fixed and adjusted dose groups.

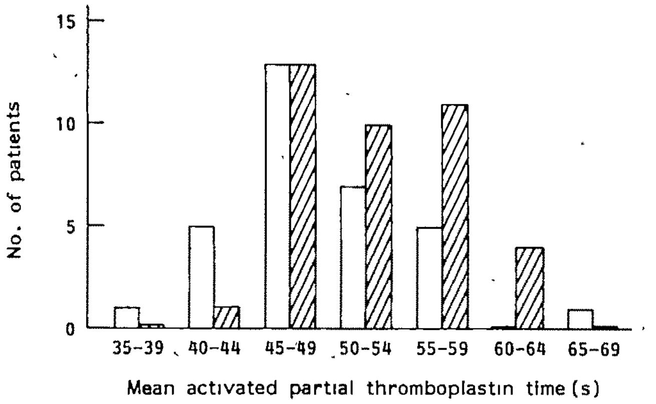

Figure 1 *Distribution of mean activated partial thromboplastin time results.* □, *fixed dose,* ■, *adjusted dose*

Discussion

The administration of fixed low dose subcutaneous heparin has been shown to be effective in the prevention of deep vein thrombosis and pulmonary embolism following major general surgery[5]. However, in certain high risk patients, such as those undergoing hip surgery, the incidence of postoperative venous thrombosis is still unacceptably high[1]. This has led to the consideration of alternative forms of prophylaxis. Alternatives, including the use of low molecular weight heparins[6] and combining low dose heparin with dihydroergotamine, have been recommended.

In a previous study, we provided preliminary data favouring an adjusted rather than fixed low dose regimen with subcutaneous heparin in hip surgery. Maintenance of a minimal prolongation of the activated partial thromboplastin time test was associated with protection from postoperative venous thrombosis without undue haemorrhage[3]. A clinical trial achieving significant benefit with an adjusted dose heparin regimen in hip surgery was subsequently published[4]. However, the mean adjusted dose of 5000 units 8-hourly was compared with a conservative fixed dose of 3500 units 8-hourly. The relative merits of the adjusted dose regimen compared with the conventional fixed dosage regimen of 5000 units 8-hourly therefore required evaluation. Our present study shows that, in hip replacement, adjusted dose subcutaneous heparin significantly improves prophylaxis compared with the fixed dose (5000 units 8-hourly) regimen. The mean heparin dose was considerably increased in the adjusted group. Excessive bleeding might therefore have been expected. The postoperative change in haemoglobin was not significantly different from the fixed dosage regimen. The measured blood loss, the volume of blood transfused and the incidence of wound haematoma were similar in both treatment groups. This indicates that adjustment, although involving a larger dose of heparin, does not increase the risk of excessive bleeding. A safety factor may have been that all patients received the same heparin dose for the first 24 h. In the hip replacement patients dose increments, where necessary, were only made after operation.

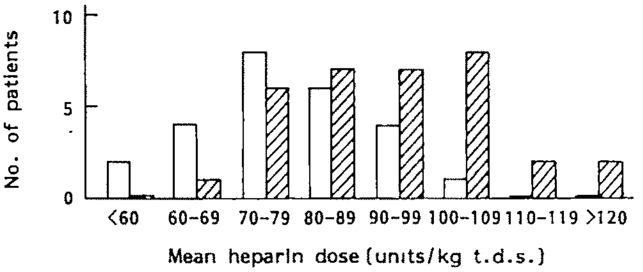

Figure 2 *Distribution of mean heparin dose·* □, *fixed dose,* ■, *adjusted dose*

Alternative techniques may be used to measure blood heparin levels but the activated partial thromboplastin time is the most widely used test for heparin control. We have shown previously that the Manchester activated partial thromboplastin time technique is suitable for monitoring the concentrations of heparin which result from low dose subcutaneous prophylaxis. It does not necessarily follow that equal success in prophylaxis of deep vein thrombosis and prevention of haemorrhage will result from heparin dose adjustment with activated partial thromboplastin time methods less responsive to the heparin effect.

Limitations in the adjusted dose approach are the demands on laboratory and clinical staff. Laboratory control involves precision in the timing and collection of blood samples and dose adjustment to keep the activated partial thromboplastin time test in the required range. Nevertheless, the regimen appears highly rewarding in preventing postoperative deep vein thrombosis during hip replacement.

Role for prazosin in reducing the development of rabbit intimal hyperplasia after endothelial denudation

Intimal hyperplasia is the universal response to endothelial denudation and occurs after a variety of vascular procedures. In a proportion of cases the smooth muscle cell proliferation may lead to stenosis of the blood vessels. These vessels exhibit increased sensitivity to noradrenaline that can be reduced by the α_1-adrenergic antagonist prazosin. Because the α_1-adrenergic receptor and platelet-derived growth factor (which promotes vascular smooth muscle cell proliferation) act through the same metabolic pathway, it was postulated that α_1-adrenergic blockade might reduce the development of intimal hyperplasia. Twenty-eight New Zealand White rabbits underwent endothelial denudation of the aorta using a Fogarty balloon catheter. Test rabbits were treated with prazosin from the day of operation until they were killed. All rabbits were killed either 1 or 4 weeks after endothelial denudation. Intimal hyperplasia in cross-sections of the aorta was measured using an X–Y digitizer and was standardized in terms of percentage luminal reduction. Prazosin-treated rabbits had significantly less luminal reduction at 1 week (0·75(1·8) versus *9·7(3·1) per cent, mean (s.d.),* P < *0·001) and at 4 weeks (14·7(4·4)* versus *25·3(12·8) per cent,* P < *0·05) than control rabbits. It is concluded that prazosin caused a major reduction in the development of intimal hyperplasia.*

Keywords: Intimal hyperplasia, prazosin, rabbit aorta, embolectomy catheter

Following vascular endothelial denudation smooth muscle cells migrate from the media across the internal elastic lamina and then proliferate to form the neointima. This sequence of events, known as intimal hyperplasia, occurs in many clinical conditions. All vein bypass grafts, whether in the aortocoronary position or more peripherally in the arterial circulation, show histological evidence of intimal hyperplasia within 12 months of surgery and as many as 25 per cent of late failures in peripheral vein grafts are a result of this thickening[1]. Following coronary angioplasty the reported incidence of restenosis is 30 per cent at 6 months[2] and after carotid endarterectomy restenosis occurs in 16 per cent at long-term follow-up[3]. Intimal hyperplasia also occurs following embolectomy procedures[4,5], renal transplantation[6] and cardiac transplantation[7].

Recent experimental studies have demonstrated that endothelial denudation and the subsequent development of intimal hyperplasia is accompanied by a selective increase in sensitivity to noradrenaline[8–11]. Increased sensitivity to noradrenaline is associated with an increased affinity in the α_1-adrenergic receptor of vascular smooth muscle cells and an associated increase in turnover in the intracellular phosphatidylinositol cycle[12].

The aetiology of intimal hyperplasia (and its role in the development of atherosclerosis) has recently been reviewed by Ross[13] and the evidence suggests a leading role for platelet-derived growth factor in stimulating vascular smooth muscle cell proliferation. Platelet-derived growth factor is thought to act by increasing turnover in the phosphatidylinositol cycle. By-products of this cycle lead to an increase in intracellular calcium which stimulates protein kinase c to promote a series of phosphorylating reactions leading to cell mitosis[14]. Thus the development of intimal hyperplasia and the associated supersensitivity to noradrenaline are connected through a common pathway: the phosphatidylinositol cycle.

This study was designed to test the hypothesis that selective blockage of the α_1-adrenergic receptors might lead to a reduction in vascular smooth muscle cell mitosis and intimal hyperplasia.

Materials and methods

Twenty-eight male New Zealand White rabbits (3–5 kg) were used. Each rabbit underwent endothelial denudation of the abdominal aorta using a Fogarty balloon embolectomy catheter Fourteen rabbits were treated with prazosin (a specific α_1 antagonist) and the degree of intimal hyperplasia was compared at 1 week and 4 weeks after endothelial denudation with a control group.

Endothelial denudation

The technique used for endothelial denudation has been described previously[9] Anaesthesia was induced using thiopentone (50–100 mg) and maintained with nitrous oxide (2 l/min) and oxygen (2 l/min) The femoral artery was identified through a groin incision and a transverse arteriotomy made. A 4Fr Fogarty catheter (Edwards Laboratories Incorporated, Santa Ana, California, USA) was introduced and advanced proximal to the level of the renal arteries (approximately 16 cm from the groin). The balloon was then inflated and withdrawn to the aortic bifurcation. This was repeated three times and then the femoral artery was ligated and the skin sutured. This procedure resulted in consistently reproducible endothelial denudation of the infrarenal abdominal aorta.

Protocol

All rabbits were caged individually, given water *ad libitum* and fed the normal rabbit chow (Purina, ICN Biochemicals, Cleveland, Ohio, USA) Test rabbits were given a single daily dose of prazosin (Pfizer Ltd , Sandwich, Kent), 4 mg per os, commencing on the morning of the balloon catheter procedure and continuing until the day the animals were killed. The rabbits were killed at either 1 or 4 weeks after endothelial denudation Thus, four groups were available for study

Tissue harvesting

The rabbits were anaesthetized after which the internal jugular vein was cannulated A 4 per cent glutaraldehyde solution was infused at arterial pressure to fix the vasculature *in situ*. A total of 200 ml was infused over a period of 20 min and the aorta was then exposed and clamped at the level of the renal arteries and at the aortic bifurcation This segment of the abdominal aorta was excised and immediately fixed in 3·7 per cent formaldehyde. This technique is a modification of that previously described by Clowes *et al*[15].

Table 1 *Percentage luminal reduction in rabbit aorta due to intimal hyperplasia*

	Luminal reduction	
	1 Week	4 Weeks
Control rabbits	9·7(3·1)* ($n=6$)	25·3(12·8)† ($n=6$)
Prazosin-treated rabbits	0·75(1·8)* ($n=7$)	14·7(4·4)† ($n=6$)

The results are expressed as mean (s.d.) percentage luminal reduction. *$P<0{\cdot}001$, †$P<0{\cdot}05$ (Mann–Whitney U test)

Histological and morphometrical methods

Tissue blocks of cross-sections of the aorta were cut at a fixed point 2 cm distal to the renal vessels. The tissue blocks were dehydrated and embedded in paraffin. Sections 6 μm thick were cut and mounted on glass slides and were stained with haematoxylin and eosin. A total of six sections were cut from each aorta. The doughnut sections were projected at a standard magnification and the outline of the layers of the vessel wall were then traced on to paper sheets. The luminal surface, internal elastic lamina and the external elastic lamina were used to outline the intima and media. Planimetry of the vessel wall layers measured the surface area of the neointima using an Apple tablet interacting with an IBM personal computer. The mean area of intimal hyperplasia for each of the animals was calculated and the mean area of intimal hyperplasia for each group was then calculated. All area measurements were performed by two observers and the interobserver standard error for individual sections was 5 per cent.

In normal vessels the intima is one cell thick and does not have any significant area and so the luminal cross-sectional area in a normal vessel is that area within the internal elastic lamina. In vessels with intimal hyperplasia the cross-sectional area is reduced in direct proportion to the degree of hyperplasia. The results are, therefore, expressed as the percentage reduction in luminal cross-sectional area due to the intimal hyperplasia.

The Mann–Whitney U test was used for statistical evaluation of the differences in intimal hyperplasia between the control and prazosin-treated groups. Results were considered significant at the $P<0{\cdot}05$ level. Variance was expressed as the standard deviation (s.d.).

Results

At the completion of the study period the mean weight gain for the four groups was similar. One prazosin-treated rabbit and two control rabbits died shortly after the balloon procedure but otherwise the balloon procedure and the prazosin were well tolerated. Thus a total of 25 rabbits were available for study.

As in previous studies using this model, intimal hyperplasia developed throughout the length of the denuded abdominal aorta. However, the intimal hyperplasia was often asymmetrical and, hence, multiple sections from each rabbit were examined.

Rabbits killed at 1 week already showed the early development of intimal hyperplasia with smooth muscle cell proliferation in the neointima. At 4 weeks, however, the degree of hyperplasia had advanced significantly with an approximate tenfold increase in intimal thickness in control rabbits (*Figure 1*). At this stage the neointima was lined by typical endothelial cells.

The prazosin-treated rabbits, both at 1 week and 4 weeks after endothelial denudation, had significantly less intimal hyperplasia than the control rabbits (*Table 1*). At 1 week the cross-sectional area in control rabbit aortas has been reduced by almost 10 per cent but in prazosin-treated rabbits it was reduced by less than 1 per cent. The difference at 4 weeks was also significant with a 25 per cent reduction in control rabbits compared with 15 per cent in prazosin-treated rabbits. Apart from the reduction in intimal thickness in prazosin-treated rabbits there was no difference detectable in the morphological appearances of the intima in treated and control rabbits.

Discussion

Occlusion of vessels following vascular procedures may be due to several factors. After procedures such as vein bypass grafting, embolectomy, angioplasty and endarterectomy early occlusion is related to platelet aggregation and/or technical errors. Later occlusion is related to the smooth muscle cell proliferation of intimal hyperplasia in a significant number of cases[1–3]. Intimal hyperplasia also predisposes to the early reapperance of atherosclerosis which is often of a particularly aggressive nature[1,7,16,17]. Thus, the unfortunate irony that our currently available techniques for managing atherosclerotic disease may themselves predispose to recurrence of the same disease process.

The rabbit is a suitable model to investigate intimal hyperplasia as endothelial denudation results in predictable smooth muscle cell proliferation[4,5,9]. A recent report has convincingly demonstrated that a similar response occurs in humans after the passage of an embolectomy balloon catheter[18]. It is well recognized that intimal hyperplasia is prevalent at anastomotic sites (in particular at the distal anastomosis of bypass grafts) and this is responsible for the continuing attention to improved surgical technique[19–21]. However, endothelial denudation is inevitable with currently available techniques and so attention has been directed at possible pharmacological intervention in the prevention of intimal hyperplasia.

While the antiplatelet agents, aspirin and dipyridamole, have been extensively investigated, the results have been equivocal and also appear to be dependent on the species studied. Hagen

et al.[22] and McCann *et al.*[23] have shown a reduction in intimal hyperplasia in primates with synthetic and autogenous vein grafts. Metke *et al.*[24] have also shown a reduction in intimal hyperplasia is canine coronary bypass vein grafts using aspirin and dipyridamole. However, Radic *et al.*[25] showed no benefit from antiplatelet therapy in rabbit aorta subjected to endothelial denudation while Murday *et al.* reported an increase in intimal hyperplasia in rabbit vein grafts[26]. Finally, while Chesebro *et al.* have demonstrated increased patency of coronary artery vein bypass grafts in human[27], other studies have shown no benefit from antiplatelet treatment[28,29]. These confusing and contradictory results are related to many factors such as the dosage of aspirin, the introduction of treatment before or after surgery and platelet function and response to aspirin in different species. For these reasons we chose not to compare prazosin with antiplatelet therapy in reducing rabbit intimal hyperplasia.

The results of this study suggest that prazosin reduces the development of intimal hyperplasia both at an early and late stage. It is known from previous studies[9] that following endothelial denudation the rabbit develops maximal smooth muscle cell proliferation within 4 weeks. Further reduction in cross-sectional area after this time is likely to be due to lipid incorporation and the development of atherosclerotic plaques. We now have evidence to suggest that prazosin will also reduce the development of this process[30].

Extensive experimental and some clinical evidence now exists to show that both atherosclerosis[31–34] and intimal hyperplasia[8–12] alter arterial function by increasing contractility in response to such naturally occurring agonists as histamine, serotonin and noradrenaline. In particular, rabbit aorta with intimal hyperplasia is supersensitive to noradrenaline and this is counteracted by the administration of prazosin[9]. Thus, if prazosin proves to be effective in reducing intimal hyperplasia in clinical studies, it may be preferred as a prophylactic agent because it would also reduce the increased sensitivity of these vessels to noradrenaline. Furthermore, it is a drug which already has an accepted place in clinical practice in the treatment of hypertension. However, the role of prazosin in preventing intimal hyperplasia in coronary artery bypass grafts is open to question as the coronary arteries have a mixed α- and β-adrenergic receptor population whereas the peripheral arterial circulation has a relatively pure α_1-adrenergic receptor population.

The usual caveats regarding the relevance of animal studies in the clinical sphere apply to the proposed use of prazosin in reducing intimal hyperplasia. However, we feel that this now deserves investigation and plan to proceed with clinical studies.

Platelet aggregability after endoscopic intravariceal injection of 5 per cent ethanolamine oleate into oesophageal varices

H. Yamaga, M. Hashizume, S. Kitano, H. Higashi and K. Sugimachi

The Second Department of Surgery, Faculty of Medicine, Kyushu University, Maidashi 3-1-1, Higashi-ku, Fukuoka 812, Japan

Correspondence to:
Dr H. Yamaga

Platelet aggregability and the coagulative and fibrinolytic systems were examined in 45 patients who underwent endoscopic injection sclerotherapy for oesophageal varices. Five per cent ethanolamine oleate, the sclerosant used, was injected into the oesophageal varices. There were significant increases in the concentrations of fibrinopeptide A, fibrinopeptide B-β-15–42 and fibrin degradation products-E after the sclerotherapy. At 1 h after the sclerotherapy the mean(s.e.m.) platelet aggregation was significantly suppressed to 71·9(4·2) per cent of that before the treatment ($P<0.01$)*. There was a gradual recovery within 1 week to the same level seen before the sclerotherapy. Thomboxane* B_2 *and 6-keto-prostaglandin* $F_{1\alpha}$*, both stable products of thromboxane* A_2 *and prostacyclin respectively, showed significant temporary increases after the sclerotherapy* ($P<0.01$)*. The peak increase in the level of thromboxane* B_2 *was noted within 1 h after the sclerotherapy and earlier than that for 6-keto-prostaglandin* $F_{1\alpha}$*. This increased ratio of prostacyclin and thromboxane* A_2 *may be related to the marked limitation in platelet aggregation.*

Keywords: Endoscopic injection sclerotherapy, 5 per cent ethanolamine oleate, platelet aggregability, prostacyclin, thromboxane A_2

Since Crafoord and Frenckner[1] first reported endoscopic injection sclerotherapy for oesophageal varices in 1939, this technique has been used with excellent results[2]. The injection of sclerosants into varices leads to a thrombogenesis[3], through chemical damage to the vessel wall. Nevertheless, the precise mechanism of the haemostatic effect of sclerotherapy has not been elucidated. There are a few reports on the coagulative and fibrinolytic systems after sclerotherapy[4–6] but platelet aggregability, *per se*, has not been fully investigated, despite it being the first step in coagulation[7]. We examined platelet aggregability in relation to prostaglandin activity after the intravariceal injection of 5 per cent ethanolamine oleate for oesophageal varices in patients with cirrhosis.

Patients and methods

Patients

This study was performed on 45 Japanese patients with oesophageal varices caused by cirrhosis All were admitted to the Second Department of Surgery, Kyushu University Hospital from June to December 1987 Thirteen patients were cases of alcoholic cirrhosis and 32 were non-alcoholic related cases (primary biliary cirrhosis in one and the others had posthepatitic cirrhosis) There were 31 men and 14 women in the series, 28 were elective and 17 were prophylactic. The mean(s d) age was 55·5(9·8) years (range 33–77 years). According to the modified Child's classification[8], 13 were Child's grade A, 15 were grade B and 17 were grade C Mean(s.e.m.) retention rate of indocyanine green at 15 min was 37 4(13 4) per cent in all patients.

Methods

Procedure of endoscopic injection sclerotherapy

Endoscopic injection sclerotherapy was performed using a transparent over-tube (K-S tube, Olympus Optical Company, Tokyo, Japan)[9] for a rapid, safer injection in the initial session and the free-hand technique was used in the following sessions The instrument used was the GIF-Q series (Olympus Optical Company). The sclerosant, 5 per cent ethanolamine oleate, was injected directly into the oesophageal varices through a 21G needle at the initial and second sessions of endoscopic injection sclerotherapy At 1-week intervals sclerotherapy was repeated until all the varices were eradicated. In all sessions of endoscopic injection sclerotherapy, the patients were given diazepam (5 mg) and pentazocine (30 mg) intravenously.

Blood samples

Blood samples were collected from the peripheral veins into plastic syringes, with the patients in a resting state. The samples were separated immediately and handled as described later The samples were collected in the early morning soon after sclerotherapy and 30 min, 1 h and 1, 2 and 6 days later.

Platelet aggregation

Platelet aggregation was examined using the Born–O'Brien method[10,11] and an aggregometer (NKK-Hematracer, Model PAT-4M, SSR Company Ltd , Tokyo, Japan). A 13 5-ml sample of blood was added to a silicon coated tube containing 1·5 ml of 3 8 per cent sodium citrate. Platelet-rich plasma was obtained by immediate centrifugation of the citrated blood at 850 r.p.m. for 7 min at 20°C. Platelet-poor plasma was prepared by centrifuging the residual plasma at 1850 r p m for 5 min at 20°C. The aggregating agent was adenosine diphosphate with a final concentration of 8 μmol The aggregation was measured for the maximum change in light transmission divided by the span of the original upper and lower limits set with platelet-poor plasma and platelet-rich plasma. All samples were tested twice within 2 h of collection.

Fibrin degradation products-E

Fibrin degradation products-E was measured by latex photometric immunoassay (LPIA)[12] using kits of LPIA-1 (Mitsubishi Chemical Industries Ltd , Tokyo, Japan). The serum was obtained from blood drawn into a Trasylol (Bayer UK Ltd., Newbury, UK) solution with a final concentration of 500 units/ml by centrifuging at 3000 r p.m. for 10 min, at room temperature

Radioimmunoassay

Plasma levels of 6-keto-prostaglandin $F_{1\alpha}$ and thromboxane B_2, stable catabolites of prostacyclin and thromboxane A_2 respectively, were determined by radioimmunoassay[13], as were fibrinopeptide A and fibrinopeptide B-β-15–42[14].

Other laboratory tests

Other laboratory tests, including prothrombin time, fibrinogen and

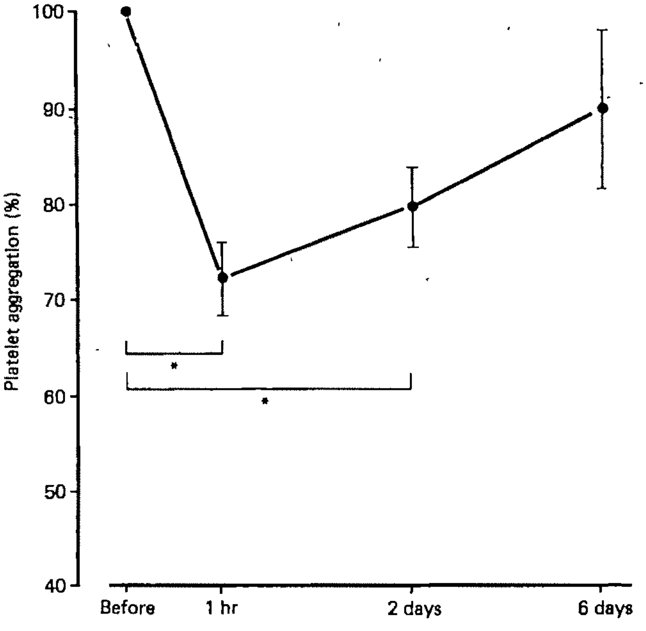

Figure 1 *Platelet aggregability was significantly suppressed at 1 h and 2 days after endoscopic injection sclerotherapy in 24 patients. Return to the preinjection level occurred on the sixth day. The vertical bars represent mean(s.e.m.).* *$P<0·01$ *(Student's* t *test)*

antithrombin III concentrations, partial thromboplastin time and platelet count, were performed in the Central Laboratory of the Kyushu University Hospital.

Statistical method

Results are expressed as mean(s.e.m.). All statistical comparisons for significance were carried out using Student's t test and a P value $<0·05$ was considered significant.

Results

Oesophageal varices were successfully eradicated in all 45 patients. The average dose of ethanolamine oleate injected into varices at the initial session was 21·7(4·6) ml. No major complications occurred. Minor temporary side-effects were retrosternal pain and low grade fever.

Platelet aggregation

One hour after endoscopic injection sclerotherapy the values of platelet aggregation significantly decreased to 71·9(4·2) per cent of that before treatment ($P<0·01$; *Figure 1*). The decrease was 79·6(4·2) per cent on the second day after injection and by the sixth day the value was close to the level seen before sclerotherapy. There was no significant difference between the degree of decrease of platelet aggregation and modified Child's classification.

Fibrinopeptide A and fibrinopeptide B-β-15–42

The concentration of fibrinopeptide A increased from the pretreatment value of 2·9(0·5) ng/ml to 7·6(1·5) ng/ml, 1 h after endoscopic injection sclerotherapy ($P<0·01$), and returned to the pretreatment level within 2 days (*Figure 2*). One hour after endoscopic injection sclerotherapy, fibrinopeptide B-β-15–42 level also showed a significant temporary elevation.

Thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$

Thromboxane B_2 significantly increased soon after endoscopic injection sclerotherapy, compared with the concentration before injection ($P<0·01$; *Figure 3*). The peak thromboxane B_2 level occurred soon after injection and returned to the preinjection level on the second day. The concentration of 6-keto-prostaglandin $F_{1\alpha}$ also increased after endoscopic injection sclerotherapy, however, the peak occurred 1 h later and by 2 days the level had almost returned to that recorded before injection.

Other laboratory data

The concentration of fibrin degradation products-E significantly increased to 191·9(33·3) ng/dl 1 h after endoscopic injection sclerotherapy (*Figure 4*). No significant change was observed in the values of antithrombin III, partial thromboplastin time and prothrombin time. Platelet count and fibrinogen values gradually increased after sclerotherapy; the platelet count was significantly increased on the sixth day ($P<0·01$). Fibrinogen levels significantly increased 1 h after endoscopic injection sclerotherapy ($P<0·01$).

Discussion

Disseminated intravascular coagulation is one possible complication of sclerosing oesophageal varices, particularly when intravariceal injections are given to cirrhotic patients with abnormal coagulative and fibrinolytic functions. Bernardi *et al.*[15] reported that endoscopic injection sclerotherapy did not lead to disseminated intravascular coagulation although transient activation of coagulative and fibrinolytic systems did occur. With a significant decrease in platelet count, an almost complete reversion was noted 18 h after endoscopic injection sclerotherapy. Our findings of increased levels of fibrinopeptide A and fibrinopeptide B-β-15–42 within 1 h after treatment also suggest activation of coagulative and fibrinolytic systems[14,16]. Platelet counts showed no significant change 1 day after endoscopic injection sclerotherapy and disseminated intravascular coagulation did not occur. However, platelet

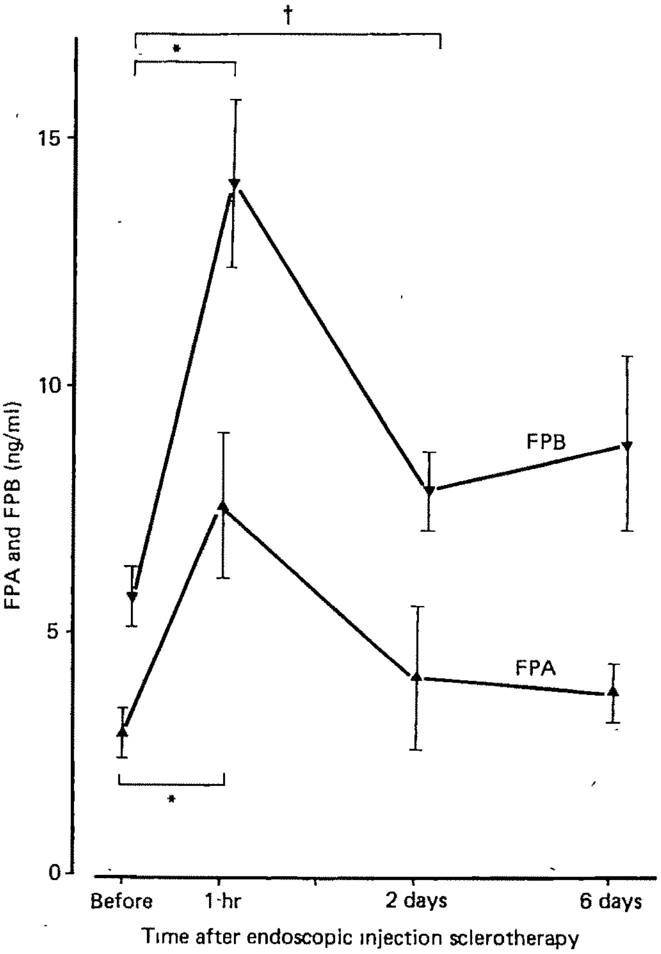

Figure 2 *Levels of fibrinopeptide A (FPA) and fibrinopeptide B-β-15–42 (FPB) were both significantly increased 1 h after endoscopic injection sclerotherapy, and fibrinopeptide B-β-15–42 was significantly increased even 2 days later, in 23 patients. The vertical bars represent mean(s.e.m.).* *$P<0·01$, †$P<0·05$ *(Student's* t *test)*

aggregability was significantly suppressed 1 h after injection. This suppression seems to have an important function in coagulative and fibrinolytic systems as platelet aggregation is the first step in these events. This suppression presumably inhibits deterioration of coagulative and fibrinolytic systems leading to disseminated intravascular coagulation.

In considering why platelet aggregation is significantly suppressed 1 h and even 2 days after endoscopic injection sclerotherapy, at least three factors have to be considered: (1) that coagulative factors such as factor XII[17] may be exhausted by activation of the coagulative and fibrinolytic systems; (2) that suppressive substances such as prostacyclin and fibrin degradation products are produced to protect against thrombus formation; and (3) that oleic acid, present in ethanolamine oleate, may directly suppress platelet aggregation18.

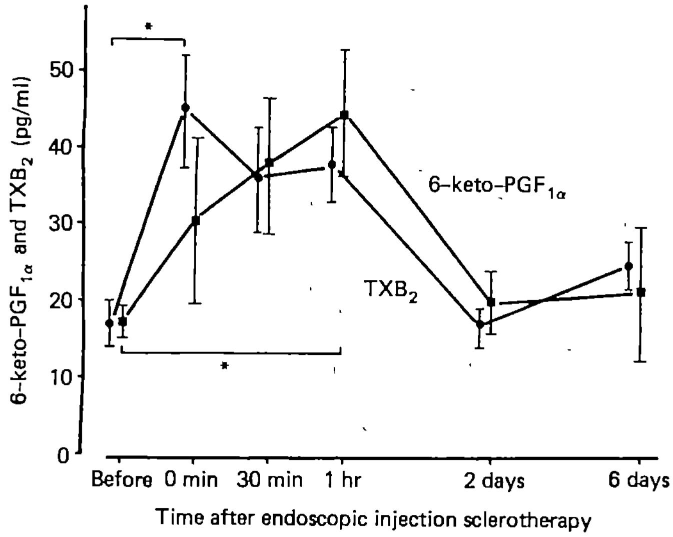

Figure 3 *The level of 6-keto-prostaglandin* $F_{1\alpha}$ *(6-keto-PGF*$_{1\alpha}$*) was significantly increased after 1 h after endoscopic injection sclerotherapy and that of thromboxane* B_2 *(TXB*$_2$*) was significantly increased soon after 1 h in 13 patients. The vertical bars represent mean(s.e.m.),* *$P<0{\cdot}01$ *(Student's* t *test)*

If coagulative factors had been exhausted then decreases in these factors would lead to a prolongation of partial thromboplastin time[19]. However, no significant prolongation occurred after endoscopic injection sclerotherapy, as was noted in other studies[5,6,15]. Fibrin degradation products and oleic acid also protect against platelet aggregation[18,20]. However, both require far higher concentrations to inhibit aggregation than were present in our study[18,20].

On the other hand, the concentration of 6-keto-prostaglandin $F_{1\alpha}$, a metabolite of prostacyclin, significantly increased after endoscopic injection sclerotherapy. This metabolite is most effective in suppressing platelet aggregation[21] as it elevates cyclic-adenosine monophosphate levels in the platelets and inhibits the release of platelet granules. Thromboxane B_2, a potent substance which induces aggregation[22], also increased in concentration after endoscopic injection sclerotherapy. The ratio of prostacyclin to thromboxane A_2 is presumably important in the suppression of platelet aggregation Thromboxane A_2 is released concomitantly with platelet aggregation after treatment, while prostacyclin is produced secondary to the release of thromboxane A_2 and stimulation of the vascular endothelium[23]. Some of the ethanolamine oleate injected enters the systemic circulation[24] and may stimulate the peripheral vascular endothelium; it does, however, injure the vascular endothelium at the site of injection[3]. The stimulation by ethanolamine oleate

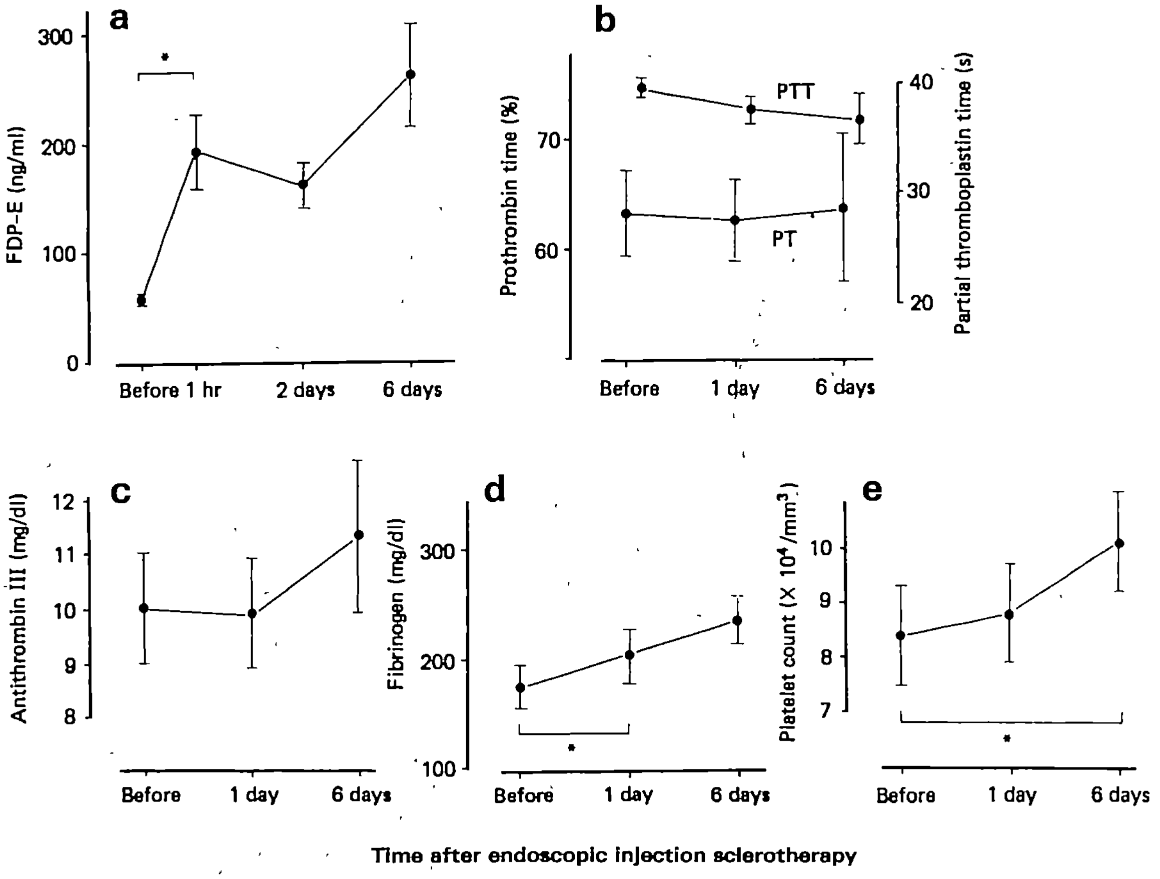

Figure 4 **a** *Fibrinogen degradation products-E (FDP-E) level,* **b** *prothrombin time (PT) and partial thromboplastin time (PTT),* **c** *antithrombin III level,* **d** *fibrinogen level and* **e** *platelet count before and after endoscopic injection sclerotherapy. Fibrin degradation products-E, fibrinogen and platelet count significantly increased in 29 patients. The vertical bars represent mean (s.e.m.);* * $P<0{\cdot}01$ *(Student's* t *test)*

presumably results in a rapid increase in production of prostacyclin in the peripheral circulation. The peak increase in concentration of thromboxane A_2 appears within 1 h, while prostacyclin increases 1 h after endoscopic injection sclerotherapy. The ratio of prostacyclin to thromboxane A_2 increases after the peak of thromboxane A_2 and is greater than that seen before endoscopic injection sclerotherapy. As these changes in prostacyclin and thromboxane A_2 are consistent with changes in platelet aggregation after endoscopic injection sclerotherapy, the production of prostaglandins may explain why platelet aggregation is greatly suppressed after injection.

In conclusion, our study suggests that platelet aggregation after intravariceal injection of 5 per cent ethanolamine oleate was significantly suppressed by a humoral response. Increase in the ratio of prostacyclin to thromboxane A_2 might prevent or at least inhibit the deterioration of the coagulative and fibrinolytic systems after endoscopic injection sclerotherapy.

Correspondence to. Dr S A Qazi

Fifty consecutive unselected patients presenting with acute haematemesis and melaena from endoscopically confirmed bleeding oesophageal varices were treated by one-stage transabdominal oesophageal transection with gastro-oesophageal devascularization and splenectomy. According to Child's classification, 15 were Grade A, 29 Grade B and six Grade C. The mortality rate was 10 per cent. Postoperative complications included gastric fundal leak (4 per cent), pleural effusion (4 per cent), subphrenic abscess (2 per cent), atelectasis (2 per cent) and pneumothorax (2 per cent). Although five patients (10 per cent) complained of transient dysphagia during follow-up, only one (2 per cent) presented evidence of stricture at the site of oesophageal transection. Clinical encephalopathy was not present in the surviving patients in the postoperative period. No recurrence of bleeding has been recorded in the surviving patients over a follow-up period of 2–3 years.

Keywords: Oesophageal transection, gastro-oesophageal devascularization, bleeding oesophageal varices

Portal hypertension with oesophageal varices is the commonest cause of acute gastrointestinal bleeding in Saudi Arabia and reflects the high incidence of schistosomiasis and hepatitis B infection in our patient population. The objective of treatment is to arrest the immediate haemorrhage, and ideally the method employed should have a minimal initial risk of morbidity and mortality and should avoid the long-term problem of rebleeding. Over the last three decades many methods have been advocated including porta azygos disconnection[1], oesophageal sclerotherapy[2], oesophageal transection[3,4], and porta caval decompression by shunt procedures[5], but the search for the ideal treatment continues. This report concerns the use of combining oesophagogastric devascularization with oesophageal transection performed transabdominally as a one-stage procedure.

Patients and methods

At the Riyadh Central Hospital all patients with acute gastrointestinal tract bleeding are admitted to the Haematemesis/Melaena Unit After appropriate resuscitative measures urgent gastrointestinal endoscopy is performed for diagnostic purposes Resuscitative measures include administration of fresh blood, fresh frozen plasma and cold gastric lavage. In patients who continue to bleed vasopressin therapy or tamponade using a Sengstaken–Blakemore tube are employed Between April 1985 and May 1986, 352 patients were admitted to the Unit and of these 116 (33 per cent) were diagnosed as bleeding from oesophageal varices Definitive treatment was undertaken by the one of the three surgical units on duty at the time of the patient's admission. Of these 116 patients, 58 were admitted under the care of the authors of this report Eight patients whose bleeding ceased during the early management refused further treatment and left the hospital against medical advice They were subsequently lost to follow-up leaving 50 patients who were treated surgically These 50 patients form the basis of this report, and all underwent transabdominal gastro-oesophageal devascularization and oesophageal transection

The age range of the patients was 21–75 years and only one patient was female Twenty-eight patients presented with haematemesis, 18 with both haematemesis and melaena and four patients with melaena alone In 34 patients with severe continuing haemorrhage, the surgical procedure was performed on the day of admission on an emergency basis. In the remaining 16 patients initial stabilization was satisfactory with arrest of haemorrhage and the operation was undertaken on the next elective operating schedule Eleven patients had a history of previous bleeding that had been treated elsewhere Five of these had undergone a Hassab devascularization procedure, another five had multiple sessions of sclerotherapy and one patient had a Warren distal splenorenal shunt.

Table 1 shows the grouping of the 50 patients according to Child's classification. *Table 2* shows the endoscopic grading of the oesophageal varices assessed by a subjective grading from I to IV corresponding to the method described by Paquet[6]. Eleven (22 per cent) patients had a positive surface antigen test for hepatitis B infection Histological examination of the operative liver biopsies showed schistosomiasis in 28 cases, posthepatitic changes in nine cases, a combination of schistosomiasis with posthepatitic changes in 12 cases and alcoholic cirrhosis in one case (*Table 3*) The diagnosis of cirrhosis was made when fibrosis was associated with structurally abnormal parenchymal nodules, and was classified as micronodular or macronodular depending on whether the nodules were less or more than 3 mm in diameter Cirrhosis was considered posthepatitic when specific features including ground glass cells and positive viral antigen were present, and alcoholic when fatty change and Mallory bodies were seen.

Diagnosis of schistosomiasis

The diagnosis of schistosomiasis was based on the following:

1 Observation of the parasite, ova or the black pigmentation in the portal spaces or in the Kupffer cells
2. The presence of typical fibrosis including wire, irregular thin-walled vascular spaces with or without evidence of schistosomiasis in other tissues, e.g. oesophageal tissue
3 The presence of granulomatous changes associated with parts of the eggs.

When schistosomiasis was associated with cirrhosis regenerative changes and architectural distortion were noted in all cases. In about 50 per cent of cases the parasite or the ova were seen while in the other cases only indirect evidence of schistosomiasis was found

Operative procedure

All patients were operated on by the same surgical team The amount of intraoperative blood transfusion and the time taken for the operative procedure were recorded Laparotomy was carried out through a bilateral subcostal incision extending to the anterior axillary line on the left side Gastric devascularization and splenectomy was performed as in the Hassab procedure. This involves both curvatures of the stomach preserving only the right gastric and right gastroepiploic vessels Oesophageal devascularization was performed up to the diaphragmatic hiatus by ligating all the collateral vessels. 5 cm of thoracic oesophagus was exposed and its feeding vessels were either cauterized or occluded with clips. Both vagi were divided. Through a small anterior gastrotomy a disposable curved EEA® stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK) was introduced into the lower oesophagus. The size ranged from 25 to 31 mm. A purse string suture was tied 1·5–2 cm above the oesophagogastric junction and the instrument then fired to complete the closed transection.

The gastrotomy incision was closed with a TA 55® stapler (US Surgical Corporation and Auto Suture, UK) and the procedure completed with a Heineke–Mikulicz pyloroplasty. The abdomen was drained with two Yeates' drains, one placed in the splenic bed and the other near the pyloroplasty site. On the third postoperative day the patient was given dilute methylene blue to swallow, the appearance of the methylene blue from the drains was indicative of a leak. Gastrografin® swallow (Schering Health Care Ltd., Burgess Hill, UK) studies were done on the fifth postoperative day to demonstrate patency of the oesophageal anastomosis or the presence of any leakage.

Results

Operative difficulties

Intraoperative bleeding (generalized oozing) due to low platelet count, prolonged prothrombin time and the presence of jaundice was overcome by the liberal use of fresh frozen plasma and platelet concentrate during surgery. Considerable oedema of the lower oesophagus was encountered in one patient because of injection sclerotherapy performed at another centre 5 days before admission to our unit. In this patient an EEA size 28 stapler was used to transect the oesophagus, and this was followed by considerable bleeding from the site of transection. Inspection of the transected doughnut showed partial transection of the thickness of the oesophageal wall. This problem was overcome by re-enforcing the anastomotic line with Vicryl® (Ethicon Ltd., Edinburgh, UK) sutures. In another patient there was considerable loss of blood from the left drain despite a normal clotting profile. Re-exploration revealed active bleeding from the splenic bed and this was dealt with accordingly. Symptomatic gallstones were found in one patient and cholecystectomy was added to the procedure. In another patient a hard mass was felt in the gallbladder wall near the fundus. This was thought to be a tumour of the gallbladder. Cholecystectomy with wedge resection of the gallbladder bed was performed. Histopathological examination revealed bilharzial granuloma from the liver infiltrating the gallbladder wall.

Postoperative morbidity

Twenty-one patients (42 per cent) showed pyrexia of no definite pattern during the postoperative period. Ten of these patients had chest infection proved by sputum cultures, two patients had pleural effusion and one patient had a subphrenic collection. The fever in these patients subsided after appropriate treatment. The remaining eight patients were pyrexic for 10–20 days without obvious cause and this subsided spontaneously without treatment.

There was no leakage at the oesophageal transection site in this series. Minor gastric leakage was encountered in two patients. In one patient a leak from the fundus of the stomach was attributed to extensive devascularization and consequent patchy necrosis. This responded well to conservative treatment. In the other patient the gastric leak occurred after draining a subphrenic collection through a posterior approach that had resulted in a left-sided pneumothorax and atelectasis. This patient was also managed conservatively with total parenteral nutrition, and was well at discharge home on the 87th postoperative day.

Mortality

Forty-four patients left the hospital 10–32 days after operation (mean 24 days). One patient left on the 87th postoperative day. The remaining five patients died during the first 2 weeks of the postoperative period, giving a mortality rate of 10 per cent. Four of those who died were patients in Child's Group C. They developed progressive hepatic failure; in one of them death was precipitated by a pulmonary embolism on the fifth postoperative day. The fifth patient (Child's Group B), who had poorly controlled diabetes and underwent emergency surgery, developed acute renal failure, later complicated by progressive hepatic failure, he died on the 10th postoperative day. Postoperative deaths occurred in one of 28 schistosomiasis patients, three of nine hepatitic patients and in one of 12 patients with combined pathology.

Follow-up

The 45 surviving patients who were under regular follow-up for a period of 2–3 years showed no symptoms or signs of hepatic encephalopathy. Six patients complained of dysphagia; only one required repeated dilatation and he remained symptom-free after the fourth dilatation session. The remaining five patients improved gradually without treatment. One patient complained of heartburn, which proved to be due to reflux oesophagitis and which reponded well to treatment with antacids. This particular patient had a very low oesophageal transection at the oesophagogastric junction.

None of the surviving 45 patients has rebled during the follow-up period. All the patients were examined by upper gastrointestinal endoscopy at 4-monthly intervals during the follow-up period. *Table 2* shows the regression in the grading of the varices.

Discussion

Bleeding from oesophageal varices presents a difficult management problem because of recurrent bleeding and its associated high mortality rate. Numerous operative procedures intended to ablate, disconnect or decongest the dilated venous collaterals of the oesophagogastric region have been devised. Sugiura and Futagawa[7] reported their technique of transthoracic oesophageal devascularization, transection and splenectomy in 1973. Later they reported the results of 276 patients dealt with over a period of 10 years[8], 60 of whom underwent the surgery for prophylactic reasons. None of our patients had surgery for prophylactic reasons. Hassab developed his own non-shunt technique and reported 355 cases in 1967[9]; of these, 151 patients were non-bleeders. By 1970 Hassab had undertaken 605 operations and reported the follow-up of 232 patients[10]. Of these, 92 patients had undergone the procedure for prophylactic reasons.

The rebleeding rate during the immediate postoperative or follow-up period is an important evaluation factor. Hassab reported a 2 per cent fatal rebleeding rate in the immediate postoperative period[9]. In a later report[11] the recurrent bleeding rate was 7 per cent and two patients required reoperation. Seven other patients were described as having had minor bleeds during follow-up. Sugiura reported a rebleeding rate of 12 per cent after Hassab's operation and 3 per cent after his own procedure[7], while Gouge and Ranson[11] reported a higher rebleeding rate of 37 per cent after the Sugiura procedure. This can be explained on the basis of the 'intact' posterior wall of the oesophagus which remains after the Sugiura procedure[8,11], while Hassab's operation does not interrupt the submucosal and intermuscular variceal veins[11,12].

Oesophageal transection alone may not prevent recurrent bleeding as ws observed by Spence[13] and Spence and Johnston[14,15]. In their procedure only the left gastric vessels were ligated and Johnston[16] reported a series of 80 patients with a rebleeding rate of 5 per cent. In a more recent series of 100 patients reported in 1985, three patients rebled in the immediate postoperative period and 11 patients rebled during the follow-up period[14]. Cooperman *et al.*[17] encountered no rebleeding in their five patients having oesophageal transection using the EEA stapling gun. In our series of 50 patients there was no rebleeding either during the immediate postoperative period or during the 2–3 years of regular follow-up. Da Silva *et al.*[18] have undertaken a randomized trial of oesophagogastric devascularization, splenorenal shunt and distal splenorenal shunt for patients with bleeding oesophageal varices due to schistosomiasis. However, the type of non-shunt devascularization procedure undertaken by these authors differs from our own in that the oesophagus is not transected; hence, a comparison cannot be drawn between the operative procedures.

In terms of operative results, none of the patients undergoing oesophagogastric devascularization had portosystemic encephalopathy as was the experience of Da Silva *et al.*[18]. However, the rate of rebleeding reported in their series was 13·3 per cent compared with nil in our series. Again we emphasize that because the submucous and intramuscular venous channels are not interrupted by their procedure, a significant rate of rebleeding can be expected. In Da Silva's series all the patients reported had schistosomal pathology[18], while in our series 44 per cent of patients had non-schistosomal pathology.

The operative time required to perform the procedure is of paramount significance in these seriously ill patients. Comparison with shunt surgery cannot be valid and our ablative procedure should be compared only with other ablative procedures. The mean operative time for Hassab's procedure is not reported[9,10], while in the Sugiura procedure the average operation time was reported as 9 h 30 min[11]. Other authorities believe that this extensive procedure is probably unnecessary for some and too dangerous for other patients[19]. The adverse effects of the length of the operative time on survival is significant. Operative procedures exceeding 6 h had a mortality rate of 70 per cent compared with 33 per cent for those taking less than 6 h[20]. In our series the average time required to perform the procedure was 3 h 45 min, with a minimum of 2 h 30 min and a maximum of 4 h 30 min.

The 'in-hospital' stay period in this series was between 10 and 32 days (mean 24 days). Only one patient stayed for 87 days because of a subphrenic collection, leak and chest infection. The average in-hospital stay for the Sugiura procedure is 30 days with a chest complication rate of 20 per cent[11], as opposed to 8 per cent in the present series. Although dysphagia occurred in six patients (12 per cent) only one required dilatation while the remaining five became asymptomatic spontaneously. This compares well with the findings in other series[14,16,21,22]. Leakage from the anastomotic site did not occur in any of our patients and the two gastric leaks detected give an incidence of leakage comparable to that of Johnston[16]. Our mortality rate of 10 per cent compares favourably with rates in other series which range from 14 to 25 per cent[9,11,19]. The five deaths in this series occurred during the postoperative period and were mainly due to liver failure The satisfactory outcome of combined gastric devascularization and oesophageal transection for bleeding oesophageal varices has encouraged us to persist with the method which is worthy of further trial and evaluation

Sham feeding for testing gastric secretory capacities before and after parietal cell vagotomy

F. Gilly, J. Chabal,
J. Boulez and
Y. Minaire

Pavillon O and INSERM U 45,
Hôpital E. Herriot, 69437 Lyon,

Professor Y. Minaire

The usefulness of acid secretory data collected during a modified sham-feeding (MSF) test was examined in 50 patients suffering from duodenal ulcer before and after parietal cell vagotomy. In these patients basal acid output pentagastrin-stimulated acid output and MSF-stimulated acid output were measured. Preoperative MSF-stimulated acid output was found to be correlated with preoperative basal acid output, and postoperative MSF-stimulated acid output was correlated with both preoperative basal acid output and postoperative basal and pentagastrin-stimulated acid outputs. The addition of preoperative MSF-stimulated acid output to preoperative pentagastrin-stimulated acid output did not noticeably increase the close relationship between the latter and postoperative pentagastrin-stimulated acid output. It is concluded that basal and MSF-stimulated secretory rates overlap. Therefore, it is suggested that in both preoperative and postoperative conditions the addition of the sham-feeding test to the more simple basal and pentagastrin-stimulated studies could be discarded.

Keywords: Duodenal ulcer, sham feeding, gastric function tests

The modified sham-feeding (MSF) test was introduced 8 years ago[1–3] as a simple, harmless and efficient vagal test, generally associated with the measurement of acid secretion but also with pepsin output[4] and plasma pancreatic polypeptide concentrations[5–9]. Combining these exocrine and endocrine parameters or not, authors have proposed MSF in an attempt to check the completeness of parietal cell vagotomy[2,10–14] or to assess vagal tone[3,8,15] to predict ulcer recurrence[11,16] or ulcer activity[4]. However, whatever the parameter considered, the usefulness of the MSF test, with respect to any of these objectives, remains debatable. The present study was designed to investigate whether there is any advantage in adding the MSF-stimulated acid secretory data to the classical basal acid output and pentagastrin-stimulated acid output parameters for the appreciation of the secretory pattern in duodenal ulcer patients both before and after parietal cell vagotomy.

Patients and methods

Patients

From March 1982 to August 1986, 50 patients (42 men, eight women) of mean age 39·7 years (range 18–68 years) with well established uncomplicated duodenal ulcers were examined 1 week before and 2 months (mean 64·7 days) after parietal cell vagotomy.

Secretory procedures

The tests were performed after an overnight fast, any anticholinergic or antisecretory medication being withdrawn at least 48 h before the study.

A multiple-lumen nasogastric tube was positioned in the fundus for gastric juice collection. Residual gastric contents were discarded, a 100-ml water recovery test was performed, and the tip of the tube was considered to be satisfactorily positioned if 80–100 ml of water were recovered. The gastric juice samples were collected by manual aspiration in 15-min periods. Pyloric losses and duodenogastric reflux were not estimated. The amount of acid collected was determined by titration to pH 7·0 with 0·1 M NaOH using an automatic titrator (Autoburette Radiometer, Copenhagen, Denmark). A basal period of 60 min was initially observed, but in order to empty the stomach totally and reach a basal secretory steady state only samples collected between $t = -30$ min and $t = 0$ were taken into account for the calculation of basal acid output in millimoles per hour. At the end of this period the subjects were served an appetizing meal consisting of about 100 g beef steak and 100 g fried mushrooms. Under constant supervision, they were asked to chew and spit out this meal during a 15 min period and were allowed to wash out their mouths with water to eliminate food particles that might otherwise be swallowed. Gastric juice was then collected between $t = +15$ and $t = +60$ min, and MSF-stimulated acid output in millimoles per hour was calculated from the two consecutive largest outputs. At the end of the MSF test period, pentagastrin (Peptavlon, ICI Pharmaceuticals, Macclesfield, UK) was injected subcutaneously (6 μg kg^{-1}) and the gastric juice was then collected in four 15-min samples, i.e. between $t = 60$ and $t = 120$ min Pentagastrin-stimulated acid output in millimoles per hour was calculated from the two consecutive largest outputs. Except during the 'meal' period, saliva was aspirated throughout the experiment. During all tests, gastric aspirates were carefully checked for swallowed particles: few or none were found.

Statistics

Examination of data showed that preoperative MSF-stimulated acid output, preoperative pentagastrin-stimulated acid output and postoperative pentagastrin-stimulated acid output were normally distributed, while preoperative basal acid output, postoperative basal acid output and postoperative MSF-stimulated acid output were not (*Table 1*). Therefore, as a rule, non-parametric Spearman rank correlations were calculated except for preoperative MSF-stimulated acid output, preoperative pentagastrin-stimulated acid output and postoperative pentagastrin-stimulated acid output, for which a standard program for multiple regression analysis was used.

Results (*Figure 1*)

The overall efficiency of parietal cell vagotomy was illustrated by a reduction of 98 per cent (median 4·10 *versus* 0·06 mmol h^{-1}), 54 per cent (median 29·40 *versus* 13·55 mmol h^{-1}) and 94 per cent (median 13·05 *versus* 0·80 mmol h^{-1}) in basal, pentagastrin-stimulated and MSF-stimulated acid outputs respectively.

Simple correlation (Spearman rank test) between preoperative basal, pentagastrin-stimulated and MSF-stimulated acid outputs showed that MSF-stimulated acid output was mainly and significantly correlated ($r_S = 0{\cdot}58$, $P < 0{\cdot}01$) with basal acid output. On the other hand, basal acid output was weakly correlated ($r_S = 0{\cdot}33$, $P < 0{\cdot}05$) with pentagastrin-stimulated acid output, while no relationship was found between pentagastrin-stimulated acid output and MSF-stimulated acid output ($r_S = 0{\cdot}26$, n.s.). Simple correlation between postoperative basal, pentagastrin-stimulated and MSF-stimulated acid outputs showed significant correlations

($P<0·01$) between basal acid output and pentagastrin-stimulated acid output ($r_S=0·43$), basal acid output and MSF-stimulated acid output ($r_S=0·49$) and MSF-stimulated acid output and pentagastrin-stimulated acid output ($r_S=0·41$). Postoperative basal acid output was not correlated with preoperative basal acid output ($r_S=0·08$, n.s.), MSF-stimulated acid output ($r_S=0·08$, n.s.) or pentagastrin-stimulated acid output ($r_S=0·14$, n.s.). Postoperative MSF-stimulated acid output was significantly correlated with preoperative basal acid output ($r_S=0·32$, $P<0·05$) but not with preoperative MSF-stimulated acid output ($r_S=0·20$, n.s.) or pentagastrin-stimulated acid output ($r_S=0·05$, n.s.). Postoperative pentagastrin-stimulated acid output was significantly correlated with preoperative pentagastrin-stimulated acid output ($r_S=0·48$, $P<0·001$) but not with basal acid output ($r_S=0·26$, n.s.) or MSF-stimulated acid output ($r_S=0·25$, n.s.). Taking into account the Gaussian distributions of preoperative MSF-stimulated acid output, preoperative pentagastrin-stimulated acid output and postoperative pentagastrin-stimulated acid output, multiple regressions were eventually calculated. They showed a significant relationship between postoperative and preoperative pentagastrin-stimulated acid output ($r_S=0·48$, $P<0·01$), which was not noticeably reinforced when preoperative MSF-stimulated acid output data were added ($r_S=0·49$).

Discussion

It is generally agreed that sham feeding is a harmless and efficient method for stimulating gastric and pancreatic vagal drive. However, it is also a cumbersome and time-consuming method, which requires the attentive participation of the patient, who must be asked not to swallow food particles. Thus the cost-efficiency ratio and therefore the usefulness of the test can be questioned when it is used in clinical practice, either to evaluate preoperative or postoperative residual 'vagal tone', or to predict or to measure postoperative acid secretory rates and thus to infer recurrence probability. Indeed, the relationship between ulcer recurrence probability and preoperative and/or postoperative acid secretory rates can be determined only by follow-up studies. Therefore the present study was not directly addressed at ulcer recurrence but was conducted to discover whether sham feeding is a useful test. In fact, authors have paid attention to criteria other than acid secretion, such as pepsin secretion[4] or plasma pancreatic polypeptide response[17]. However, in duodenal ulcer patients and healthy controls, it has not been possible to discover any correlation between pancreatic polypeptide response and acid secretory rates[7,8]. Moreover, in duodenal ulcer patients before and after parietal cell vagotomy, Forichon *et al*[9] observed that neither basal pancreatic polypeptide concentrations nor MSF-induced pancreatic polypeptide responses showed any correlation with the corresponding acid values, and they suggested that plasma pancreatic polypeptide concentrations cannot be used as an endocrine marker of the vagal impulses delivered to the oxyntic mucosa either before or after parietal cell vagotomy. Therefore it remains to focus on acid secretory parameters and to evaluate the importance of information added by the MSF test to simpler and more classical basal acid output and pentagastrin-stimulated acid output rates. Our results show that preoperative MSF-stimulated acid output is highly correlated with preoperative basal acid output, but does not display any relationship with postoperative parameters. Moreover, the addition of preoperative MSF-stimulated acid output data to preoperative pentagastrin-stimulated acid output data does not increase the close relationship of the latter with postoperative pentagastrin-stimulated acid output values. On the other hand, postoperative MSF-stimulated acid output is closely correlated with postoperative basal acid output, postoperative pentagastrin-stimulated acid output and preoperative basal acid output. Therefore, the present analysis suggests that preoperative MSF-stimulated acid output, formerly proposed as a tool to assess vagal tone[3,8,15], could be simply replaced by preoperative basal acid output. Postoperatively, it is unlikely that MSF-stimulated acid output could add any original information to that already provided by postoperative basal or pentagastrin-stimulated acid outputs and, therefore, that it could be eventually of some help in the assessment of the completeness of vagotomy or the risk of recurrence.

In conclusion, for the sake of simplicity it is suggested that the MSF test could be deleted from routine secretory gastric testing before and after parietal cell vagotomy.

Anterior lesser curvature seromyotomy combined with posterior truncal vagotomy has been suggested as an alternative to proximal gastric vagotomy in the treatment of peptic ulcer. The argon laser may be an ideal instrument for performing seromyotomy. This study compares anterior lesser curvature argon laser seromyotomy/posterior or truncal vagotomy with anterior proximal gastric vagotomy/posterior truncal vagotomy in a canine preparation. Six dogs underwent anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy and six others underwent anterior proximal gastric vagotomy/posterior truncal vagotomy. Gastric emptying and acid secretion studies were performed preoperatively and at 1 and 6 months postoperatively. Operating time and blood loss were determined. Anterior lesser curvature argon laser seromyotomy was performed with the argon laser at 10 W, continuous, delivered through a 600 μm unsheathed quartz fibre. Anterior proximal gastric vagotomy and posterior truncal vagotomy were performed in the standard fashion. Solid phase gastric emptying was slowed with both operations ($P<0{\cdot}05$) *but this was not manifest clinically. Blood loss (millilitres) was less following anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy than following anterior proximal gastric vagotomy/ posterior truncal vagotomy (21(6·8)* versus *95(28·1), mean (s.e.m.),* $P<0{\cdot}05$) *but operating time was not significantly different between the groups. Mean basal acid secretion was reduced by 64 per cent 6 months after anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy* ($P<0{\cdot}05$) *and by 53 per cent after anterior proximal gastric vagotomy/posterior truncal vagotomy (not significant). Mean stimulated acid secretion was reduced by 41 per cent 6 months after anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy* ($P<0{\cdot}05$) *and by 24 per cent after anterior proximal gastric vagotomy/posterior truncal vagotomy (not significant). We conclude that anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy is an acceptable alternative to anterior proximal gastric vagotomy/posterior truncal vagotomy and may provide superior parietal cell denervation with less operative blood loss.*

Keywords: Laser, peptic ulcer disease, vagotomy, seromyotomy

Proximal gastric vagotomy can be a technically demanding operation and is associated with a high rate of recurrent ulceration[1–4]. Several derivative procedures have been designed to reduce the rate of ulcer recurrence[5,6]. An operation designed to improve parietal cell denervation and decrease operating time is anterior lesser curvature seromyotomy combined with posterior truncal vagotomy. While anterior lesser curvature seromyotomy/posterior truncal vagotomy is an attractive alternative to proximal gastric vagotomy this innovative procedure has several potential disadvantages. Sharp dissection of the anterior seromuscular layer of the stomach may cause excessive blood loss and occasional mucosal perforation. An 'overlap repair' of the seromuscular incision is necessary to reinforce the stomach and to prevent reunion of vagal nerve fibres[6]. These limitations may be reduced by the use of the argon laser which creates a predictable shallow injury and is an excellent instrument for the coagulation of small blood vessels[7]

This study compares the technique and results of anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy with anterior proximal gastric vagotomy/posterior truncal vagotomy in a canine preparation

Materials and methods

Experimental design

This study was performed in three phases. In phase one the optimal argon laser dosimetry for 'safe' seromyotomy was determined Phase two was an acute, qualitative study of parietal cell denervation produced by anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy. Phase three was a chronic quantitative study in which anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy was compared with anterior proximal gastric vagotomy/posterior truncal vagotomy in 12 dogs. All dogs were cared for in accordance with the National Research Council's guide for the care and use of laboratory animals

Phase 1 laser dosimetry

Under barbiturate anaesthesia a midline celiotomy was performed in two dogs. Argon laser energy (HGM Endo-20, HGM Corporation,

© 1989 Butterworth & Co (Publishers) Ltd

Salt Lake City, Utah, USA) was delivered through a 600 μm unsheathed quartz fibre (beam divergence 5°, spot size 2 mm). The fibre was held perpendicular, 1 cm from the gastric serosa. Linear applications were made varying the power from 2 to 15 W. The optimal laser power was defined as the minimum power necessary to divide all nerve fibres, coagulate small vessels and cause blanching of the stomach wall when the laser beam was manually moved at 1 cm/s. Multiple linear applications were then made at optimal power. Spot applications at optimal power were made at a single 2 mm spot for 1–5 s Seven days later the animals were killed and samples from each injury site were taken for histological examination.

Phase 2. acute, qualitative studies

Three 25-kg dogs underwent midline celiotomy. A long anterior gastrotomy was made and the gastric mucosa was exposed. The mucosa was neutralized with 5 per cent $NaHCO_3$ and irrigated with normal saline. Pentagastrin® (Ayerst Laboratories, New York, USA) 6 μg/kg was injected subcutaneously. One per cent congo red, an indicator dye which turns black at pH <3, was applied to the gastric mucosa and the percentage of acid secreting mucosa was estimated

Anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy was then performed: 3 cm of distal oesophagus were cleared and a posterior vagotomy was performed. The anterior vagus nerve was preserved Several large branches of the left gastric artery and vein were divided on the high lesser curvature. An unsheathed argon laser fibre (10 W, as determined in phase one) was held perpendicular, 1 cm from the gastric wall. The seromyotomy was started at the angularis incisura, 1 cm in from the lesser curvature. The laser beam was advanced along the lesser curvature at 1 cm/s, dividing all nerve fibres from the first branch of the 'crow's foot' to the cardio-oesophageal angle The congo red test was repeated.

A fourth dog underwent only anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy at initial operation. Seven days later gastrotomy and congo red assay were performed. The laser seromyotomy site was serially sectioned and examined histologically.

Phase 3 chronic quantitative studies

Twelve 25-kg mongrel dogs were subjected to a 6-month trial comparing anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy with anterior proximal gastric vagotomy/posterior truncal vagotomy. The dogs were randomized to treatment groups by tag number. Each animal served as its own control. Before operation each animal underwent solid phase gastric emptying evaluation and gastric acid secretion analysis.

Gastric emptying. Solid phase gastric emptying was assessed with a 50-g ^{99m}Tc-labelled liver meal administered after a 24-h fast. The fraction of marker remaining in the stomach was measured on completion of the meal and then every 10 min until 50 per cent of the marker had passed into the intestine. The animals were unrestrained between each 30 s γ camera acquisition period. Images were displayed on the computer screen and a region of interest was placed around the stomach. The stomach radioactivity was corrected for radioactive decay and the time to half-emptying ($t_{\frac{1}{2}}$) was calculated using linear regression curve fitting to the data[8].

Gastric acid secretion. Acid was collected by gastric aspiration[9,10]. After a 24-h fast each animal was anaesthetized with sodium pentobarbital and placed in the right lateral decubitus position. A femoral artery catheter was inserted for continuous monitoring of blood pressure. Two 14 Fr orogastric sump tubes were placed in the stomach. With fluoroscopy, the tip of one tube was positioned in the prepyloric antrum and the second tube was positioned immediately below the gastroesophageal junction Low intermittent suction (40 cmH_2O) was applied to the distal tube. Polyethylene glycol (2·5 per cent) in isotonic saline (pH adjusted to 5·0) was infused through the proximal tube at a rate of 3·3 ml/min. The stomach was lavaged with isotonic saline and all fluid was removed. Subsequently, all gastric fluid was continuously aspirated through the distal tube and collected every 15 min After 15 min of aspiration under basal conditions pentagastrin (6 μg/kg) was injected subcutaneously. Antral aspiration was continued for a further 90 min. The hydrogen ion concentration of each aliquot was determined by the glass electrode technique[11]. Polyethylene glycol concentration was assessed turbidometrically[12]. Fractional polyethylene glycol recovery and HCl secretion were calculated[10] After the first six assays it became apparent that polyethylene glycol infusion was unnecessary as there was minimal transpyloric loss of marker. Basal acid output (millimoles per hour) was the amount of acid recovered in the 15 min before pentagastrin administration multiplied by four. Stimulated acid output was the amount of acid recovered 1 hour after subcutaneous pentagastrin.

Operation. After preoperative studies and randomization, six animals underwent anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy and six underwent anterior proximal gastric vagotomy/posterior truncal vagotomy Anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy is described above. Anterior proximal gastric vagotomy was performed in a conventional fashion[2] The operative procedures were performed by a surgeon well experienced with gastric operations (J.B.) and by a senior surgical resident (J.H.). Blood loss for each procedure was determined by sponge weight.

Follow up Gastric emptying evaluation was performed 6 weeks postoperatively Basal and stimulated gastric acid secretion were measured 1 and 6 months after operation

Statistical analysis

The Wilcoxon signed rank test was used to compare results before and after operation in each animal. The Wilcoxon rank sum test was used to compare results in animals undergoing anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy with animals undergoing anterior proximal gastric vagotomy/posterior truncal vagotomy. All results are listed as mean (s.e.m.).

Results

Phase 1: laser dosimetry

Consistent neurolysis was achieved with the argon laser at 10 W, continuous wave, when the laser was advanced at a rate of 1 cm/s. This corresponds to an average energy fluence (laser dose) of 63·6 J/cm^2. This mode of application caused only partial thickness injury of the gastric wall (*Figure 1a*). Full thickness injury occurred when the argon laser at 10 W was held on one 2 mm spot for 5 s. This corresponds to an average energy fluence of 1592 J/cm^2, 25 times greater than the energy fluence needed to perform adequate seromyotomy (*Figure 1b*). No gross perforations occurred in any of these studies.

Phase 2: acute studies – qualitative assay

Before operation approximately 50 per cent of the parietal cell mass achieved pH <3·0 after pentagastrin stimulation. Following anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy the parietal cell mucosa with pH <3·0 after pentagastrin stimulation was estimated to be nil, 2 and 5 per cent in the three experimental animals. In the animal surviving 1 week after anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy <5 per cent of the parietal cell mucosa attained a surface pH <3. Acid secreting mucosa 'missed' by anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy was located on the lesser curvature at the junction of the antrum and body of the stomach.

Phase 3: chronic studies – quantitative assay

Gastric emptying. Before operation, mean (s.e.m.) solid phase gastric emptying $t_{\frac{1}{2}}$ was 69(11·3) and 53(8·2) min for the animals randomized to anterior proximal gastric vagotomy/posterior truncal vagotomy and anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy respectively (n.s.). After operation, mean $t_{\frac{1}{2}}$ was 101(20·8) and 77(10·9) min for animals undergoing anterior proximal gastric vagotomy/posterior truncal vagotomy and anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy respectively (n.s.). Solid phase gastric emptying was slowed significantly and equally by either operation ($P<0·05$). This delay was not manifest clinically as no animal developed anorexia, weight loss or vomiting after either procedure.

Gastric acid secretion. Anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy reduced basal acid output at 6 months and pentagastrin-stimulated acid output at 1 and 6 months after the operation ($P<0\cdot05$; *Table 1*). Although reductions in basal acid output and stimulated acid output were seen after anterior proximal gastric vagotomy/posterior truncal vagotomy, they did not reach statistical significance.

Operation. The mean (s.e.m.) operative time for anterior lesser curvature argon laser seromyotomy was 20·7(1·6) min and for anterior proximal gastric vagotomy was 27·2(3·2) min (n.s.). The mean operative blood loss for anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy was 21·0(6·8) ml and for anterior proximal gastric vagotomy/posterior truncal vagotomy was 95·0(28·1) ml ($P<0\cdot05$). There were no complications resulting from surgery in either group.

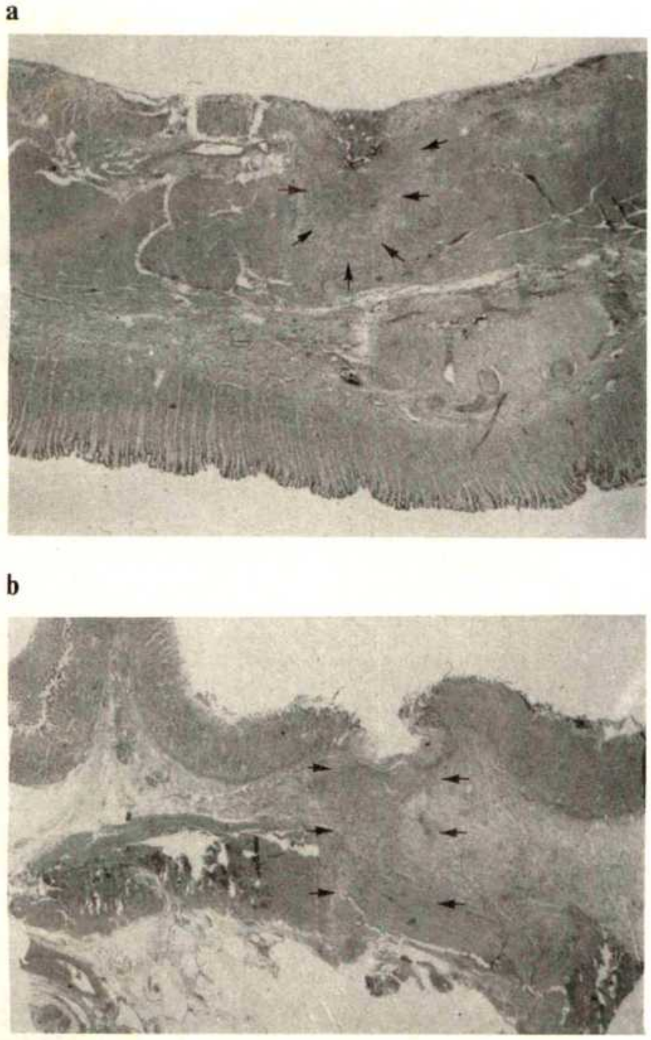

Figure 1 *Gastric wall injury 7 days after argon laser serosal application:* **a** *with argon 10 W continuous wave advanced at 1 cm/s (energy fluence 63·6 J/cm^2) a partial thickness injury was produced (arrows);* **b** *full thickness injury occurred (arrows) when the argon laser at 10 W was held in one spot for 5 s (energy fluence 1592 J/cm^2)*

Discussion

Anterior lesser curvature seromyotomy/posterior truncal vagotomy, first described in 1982[6], has recently been compared with proximal gastric vagotomy in a prospective randomized trial of 91 patients followed for a median of 3 years[13]. Postoperative complications, postoperative peak acid output, patient satisfaction and ulcer recurrence rates were the same after both procedures. Anterior lesser curvature seromyotomy/posterior truncal vagotomy was performed in a shorter time with fewer difficulties than proximal gastric vagotomy.

In this animal study we have demonstrated that anterior lesser curvature seromyotomy/posterior truncal vagotomy performed with an argon laser produces superior acid reduction to anterior proximal gastric vagotomy/posterior truncal vagotomy. While the finding that anterior proximal gastric vagotomy/and posterior truncal vagotomy produced no significant reduction in acid output may have resulted from a small sample size, it appears that anterior lesser curvature argon laser seromyotomy provided greater parietal cell denervation than anterior proximal gastric vagotomy. Possible mechanisms for superior denervation with anterior lesser curvature argon laser seromyotomy are: (1) severed nerve fibres may have regrown to a greater extent following anterior proximal gastric vagotomy than following anterior lesser curvature argon laser seromyotomy; (2) nerve fibres and ganglion cells in the myenteric plexus of the stomach are destroyed with anterior lesser curvature argon laser seromyotomy as this layer is within the penetration depth of the argon laser. Destruction of these intramural neurons may provide more complete parietal cell denervation after anterior lesser curvature argon laser seromyotomy than occurs after anterior proximal gastric vagotomy; (3) small vagal branches may have been missed with anterior proximal gastric vagotomy but not with anterior lesser curvature argon laser seromyotomy, a plausible explanation given the simplicity of anterior lesser curvature argon laser seromyotomy.

Reduction in acid secretion following anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy in our canine model is similar to that reported in clinical series of anterior lesser curvature seromyotomy/posterior truncal vagotomy. In one series of 29 patients undergoing anterior lesser curvature seromyotomy/posterior truncal vagotomy, 6 month postoperative basal acid output and stimulated acid output were reduced to 60 per cent and 40 per cent of preoperative values respectively[14]. At 6 months our values for basal acid output and stimulated acid output reduction following anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy were very similar at 64 and

Table 1 *Basal and stimulated acid secretion following anterior lesser curvature laser seromyotomy with posterior truncal vagotomy and following anterior proximal gastric vagotomy with posterior truncal vagotomy*

	Basal acid output (mmol/h)			Stimulated acid output (mmol/h)		
	Preoperative	Postoperative		Preoperative	Postoperative	
		1 month	6 months		1 month	6 months
Anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy	3·9(0·73)	4·4(0·80)	1·4(0·93)*	34·1(5·2)	19·5(4·6)*	20·2(5·1)*
Anterior proximal gastric vagotomy/posterior truncal vagotomy	7·2(1·9)	5·4(1·4)	3·4(1·2)	32·0(4·0)	18·1(3·8)	24·3(2·9)

All values are mean and s.e.m.; *$P<0\cdot05$ when compared with preoperative acid output (Wilcoxon rank sum test)

41 per cent respectively. The method of gastric acid secretion analysis was identical in both studies.

Solid phase gastric emptying, as determined by radionuclide scintigraphy, was delayed after both anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy and anterior proximal gastric vagotomy/posterior truncal vagotomy. It has been well shown in canine studies[15] and several clinical series that preservation of a single nerve of Latarjet is sufficient to maintain normal gastric emptying[6,13,14,16–18]. Unlikely explanations for delayed gastric emptying are consistent inadvertent anterior vagus nerve injury or persistent postoperative gastric ileus. Despite radiological evidence of delayed gastric emptying none of the experimental animals developed clinical evidence of gastric stasis.

Anterior lesser curvature seromyotomy/posterior truncal vagotomy has rarely produced gastric stasis in humans. In a co-operative series of 605 patients undergoing anterior lesser curvature seromyotomy/posterior truncal vagotomy, 1·7 per cent developed symptomatic gastric stasis, a drainage procedure was required in 1·3 per cent and 0·33 per cent developed diarrhoea[16]. Solid phase gastric emptying studies performed after anterior lesser curvature seromyotomy/posterior truncal vagotomy have shown no delay in emptying with this procedure.

The major advantages of lesser curvature seromyotomy over parietal cell vagotomy are speed and safety. In our study, the mean time required to perform anterior lesser curvature argon laser seromyotomy was 25 per cent less with that required to perform anterior proximal gastric vagotomy, a speed advantage commented on in most clinical series of anterior lesser curvature seromyotomy/posterior truncal vagotomy[13,14,17]. The risk of injuring the nerve of Laterjet is less with anterior lesser curvature seromyotomy/posterior truncal vagotomy than with proximal gastric vagotomy because the seromyotomy incision occurs 2·5 cm away from the nerve[6]. While no perforations have occurred with anterior lesser curvature seromyotomy/ posterior truncal vagotomy, ischaemic necrosis of the lesser curvature is a known complication of proximal gastric vagotomy. A recent investigation of lesser curvature blood flow after proximal gastric vagotomy found an average decrease in mucosal blood flow of 57 per cent and many areas were found where the mucosal blood flow had been critically diminished[19].

If anterior lesser curvature seromyotomy/posterior truncal vagotomy is technically easy, is associated with only rare complications and provides results as good as proximal gastric vagotomy, what advantages can the argon laser possibly confer? The theoretical attractions of anterior lesser curvature argon laser seromyotomy are haemostasis, speed and safety. The mean blood loss following anterior lesser curvature argon laser seromyotomy/posterior truncal vagotomy in this study was 22 per cent of the blood loss following anterior proximal gastric vagotomy/posterior truncal vagotomy. Laser seromyotomy results in diminished blood loss because small vessels are coagulated as they are cut with the laser. Laser seromyotomy may be performed more rapidly than sharp seromyotomy because there is no need to reinforce the seromyotomy incision with an 'overlap repair'. While inadvertent mucosal laceration occasionally occurs with sharp dissection, it is nearly impossible to create a transmural gastric injury with the argon laser. In a worst case analysis, transmural necrosis with the argon laser required an energy fluence 25 times that necessary for seromyotomy. Even at this energy level gross perforation did not occur. While these factors provide a conceptual advantage to laser use, it will be necessary to compare laser with sharp seromyotomy under well controlled conditions before claiming the superiority of argon laser seromyotomy over conventional seromyotomy.

Early prediction of late incisional hernias

A. V. Pollock and M. Evans

Scarborough Hospital, Scalby Road, North Yorkshire YO12 6QL, UK
Correspondence to: Mr A. V. Pollock

Incisional (ventral) hernias may not be discovered until many months after operation[1,2]. This has led to the belief that aponeuroses that have healed edge to edge may gradually part and permit the development of a hernia[2]. An alternative hypothesis is that a gap forms between the edges of the divided aponeurosis soon after operation, and that the weak fibrous tissue filling that gap gradually stretches until a hernia becomes detectable. The present study was carried out to test the validity of this hypothesis.

Patients and methods

After 163 major laparotomies, pairs of stainless steel haemostatic clips (Ligaclips®, Ethicon Ltd., Edinburgh, UK) were attached opposite each other to the edges of the sutured aponeurosis before closure of the skin. All patients were seen in the outpatient department about 1 month later and agreed to have abdominal radiographs taken, the purpose having been explained to them. The radiographs were taken postero-anteriorly, and the separation between pairs of clips was measured.

Patients were followed up at intervals. Herniation was diagnosed if a bulge appeared when the patient stood and coughed and a defect could be felt in the aponeurosis. The examining surgeon had no knowledge of the results of the radiographs taken at 1 month; these measurements were recorded on the research forms, not in the case notes. The presence or absence of an incisional hernia was checked at later follow-up examinations.

Of the 163 patients, 14 were withdrawn: in six several of the clips had fallen out because of wound infections and the radiographs at 1 month could not be assessed; five patients died within 6 months of operation; one incision was reopened within 6 months; two were lost to follow-up after the 1-month visit.

Results

The details of the remaining 149 patients are shown in *Table 1*. Radiographs from 131 patients showed minimal separation (less than 12 mm) between opposing pairs of clips, and only one patient developed an incisional hernia. She was a thin woman aged 80 years who had had a resection of the left colon for cancer through a lower midline incision that was closed with a continuous mass nylon suture. Radiographs at 1 month showed no separation of the clips, and 6 months after operation there was no sign of an incisional hernia. At 12 months, however, a bulge was seen beneath the upper half of the scar. Two years after the operation she had no complaints and was discharged. The remaining 130 patients in this group were followed up for between 6 and 75 months (median 25 months), and none showed clinical signs of incisional herniation.

There were 18 patients whose radiographs at 1 month showed separation of pairs of clips of 12 mm or more (median 40 mm, range 12–70 mm). One woman (aged 79 years at the time of operation) was reported by her general practitioner to have no incisional hernia 29 months after repair of a perforated duodenal ulcer through a midline incision that was closed with a continuous mass nylon suture; the radiograph at 1 month had shown separation of the upper two of three pairs of clips of 33 and 40 mm, the lowest pair being together.

The remaining 17 patients all developed hernias. One required repair and one a supporting belt; the rest had no symptoms. Eight of these hernias were discovered within 6 months of operation, three more at a year, and the remaining six at 16, 24, 28, 29, 36, and 43 months.

Discussion

This study is an extension and long-term follow-up of the pilot study published in 1986[3]. We found only one exception to the rule that wide separation of the anterior aponeurosis within a month of laparotomy predicts the subsequent development of an incisional hernia, and one exception to the rule that patients whose aponeuroses have healed in close apposition do not subsequently develop hernias.

Several variables were associated with higher rates of early separation of the aponeurotic suture line and subsequent herniation. Significant in the present study were emergency or urgent operations, and postoperative wound discharges (in both cases Fisher's exact probability = 0·001). The higher incidences of aponeurotic separation in midline incisions compared with paramedian, lateral paramedian, and transverse incisions, and in those sutured *en masse* rather than in layers, were not significant, but the type II error is obvious. Significantly lower rates of herniation in paramedian and lateral paramedian incisions have been reported[4,5].

Perhaps we should have arranged radiographs for our patients sooner than 1 month after operation—it may be that

0007–1323/89/090953–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

separation of the aponeuroses occurs within the first few days. This is a question yet to be answered.

Combination chemotherapy is more effective in postspillage prophylaxis for hydatid disease than either albendazole or praziquantel alone

D. H. Taylor and D. L. Morris

Department of Surgery, University of Nottingham, Nottingham, UK
Correspondence to: Dr D. L. Morris

Recurrence is one of the most significant postoperative complications following surgery in man for *Echinococcus granulosus*, occurring in approximately 10 per cent of patients[1]. When recurrence occurs, further surgery is associated with increasing morbidity and mortality[2]. It has previously been reported that a short course of oral albendazole after spillage of viable protoscolices can significantly reduce the risks of cyst development in a gerbil model[3] and that the timing of albendazole prophylaxis to spillage was of great importance[4]: it was ineffective when given 15 days later. The isoquinoline praziquantel has been found to be a more effective scolicidal agent in *in vitro* cultures of *E. granulosus*[4]. We have previously shown that combinations of albendazole and praziquantel are more effective than either agent alone in *in vitro* culture[5]. In this paper we study *in vivo* results in an animal model of peritoneal spillage.

Materials and methods

Thirty-nine gerbils were each injected intraperitoneally with approximately 4000 viable protoscolices obtained from viable ovine cysts of *E. granulosus*. The gerbils were divided into a control and three treatment groups: ten received a 1-month course of albendazole (50 mg kg^{-1} day^{-1}), ten received a 1-month course of praziquantel (500 mg kg^{-1} day^{-1}) and ten gerbils received 1 month of a combination of praziquantel (500 mg kg^{-1} day^{-1}) and albendazole (50 mg kg^{-1} day^{-1}). All drugs were given by once daily gavage starting within 24 h of intraperitoneal infection. The remaining nine animals became the infected untreated controls. Eight months after inoculation, the gerbils were killed. The number of cysts in each animal in each group was measured at necropsy. The Mann–Whitney U test was used.

Results

All the gerbils survived until the end of the experiment. It was found that the number of cysts developing in any of the three test groups (albendazole treated mean (s.d.) 22·6(10·0) cysts per gerbil, praziquantel treated 5·9(1·09) and combination treated 0·8(0·29)) was significantly less ($P<0{\cdot}01$) than the number developing in the controls (67·6(12·8) cysts per gerbil). It was also found that a combination of the two drugs was significantly more effective ($P<0{\cdot}001$) than when either drug was given alone. Praziquantel alone showed a trend to more effective reduction of the number of cysts at this particular dosing regimen, compared with albendazole ($P<0{\cdot}1$).

Discussion

We have previously shown that even 7 days treatment with albendazole after intraperitoneal inoculation of protoscolices of *E. granulosus* in a gerbil model host can reduce the number of cysts that develop.

In vitro culture of protoscolices has shown their sensitivity to the isoquinoline praziquantel[6,7]. We have also defined the minimum concentrations and time of drug exposure[8,9]. Praziquantel is an active scolicidal agent at concentrations as low as 20 μg litre^{-1} (compared with 250 μg litre^{-1} of albendazole sulphoxide) and exposure time can be as low as 30 min at a high concentration[10]. Albendazole does however have a proven effect on the germinal layer of the parasite[11], and this drug may be useful in the postoperative patient where tiny undetected cysts may remain. This study clearly demonstrates that combined chemotherapy with albendazole and praziquantel in an animal model is more effective than either agent when given alone, and should be considered in clinical practice.

1988 SURGICAL UPDATING
First World Postgraduate Surgical Week of the University of Milan
XXVI World Congress of the International College of Surgeons
Milan, July 3-8, 1988
MONDUZZI EDITORE

It is with great satisfaction that I introduce these volumes containing the presented papers in the free-papers session of the First World Postgraduate Surgical Week of the University of Milan — XXVI World Congress of the International College of Surgeons.

The actuality of the topics, which go from those belonging to the future to those of more common finding, and the authority of the speakers, practically representing the best Surgical Schools both International and National, make of these volumes a complete updating of General Surgery and of all Surgical Specialties.

The variety of the topics covered and the universality of the Authors testify to the complexity of this uncommon scientific-editorial endeavour; I am therefore deeply grateful to all those who have in various manners participated in this effort.

The work is divided into two sections:
— 3 volumes covering the full official papers
— 13 volumes covering free papers.
All volumes are available for immediate despatch.

Prof. Walter Montorsi

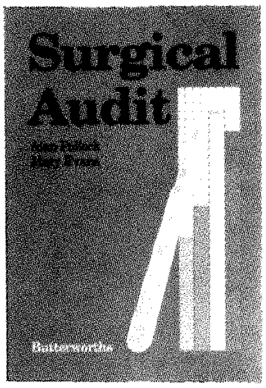
Surgical Audit

Alan Pollock BSc FRCS FRCS(Ed)
Consultant Surgeon, Department of Surgery,
Scarborough Hospital, Scarborough, UK

Mary Evans BA
Research Co-ordinator, Department of Surgery,
Scarborough Hospital, Scarborough, UK

★ **written by acknowledged experts in the field**
★ **essential reading for all surgeons with the increasing demands for quality control, patient satisfaction and cost effectiveness**
★ **enables surgeons to set up and evaluate their own audit systems**

This book provides practical advice on how surgeons can evaluate the various facets of surgical practice and their effective management.



Surgical Audit will be an essential book for all practising and trainee surgeons and will be welcomed by hospital administrators and all those involved in the day-to-day running of surgery departments.

Contents: The history of audit • The evolution of surgical audit • What is audit? • Economic audit introduction • Economic audit: reducing hospital stay • Diagnosis related groups and performance indicators • The containment of costs in surgery • The containment of costs of health care in the USA • Recording, retrieval and analysis of clinical data • Introduction to audit of outcome • An example from the SENIC program • Random control trials • Confidential enquiry into perioperative deaths • Quality of life after surgery • Mishap and malpractice • Measures to encourage professional competence • Introduction to audit of patient satisfaction • Waiting for hospital treatment • The sanctity of life • Clinical surgery • Human experimentation • Peer review of papers submitted to scientific journals • Audit of surgical publications • The presentation of audit of outcome • Index

Conservative treatment of ingrowing toenails

J. A. M. Reijnen and R. J. A. Goris

Department of General Surgery, University Hospital St. Radboud, Geert Grooteplein zuid 14, Postbus 9101, 6500 HB Nijmegen, The Netherlands

Correspondence to: Dr. J. A. M. Reijnen

A combination of conservative measures was used to treat 105 patients with 119 ingrowing toenails. The method proved to be simple and cheap, but time consuming. Post-treatment discomfort and the time taken to return to normal activities were acceptable; the cosmetic result was good. Two-year follow-up revealed that the success rate of the method in less advanced cases (stages I and II) was high (96 per cent), although in the long term there was a tendency to recurrence in stage II cases. The failure rate in advanced cases (stage III) was high (up to 62 per cent). Conservative treatment can be used successfully in mild cases of ingrowing toenails.

Keywords: Ingrowing toenails, conservative treatment

Ingrowing or, more accurately, embedded toenails are a common cause of pain and discomfort and can occur in any person of any age but are most common in male adolescents. There is little uniformity in treatment as the method should satisfy several criteria· the procedure should be simple and cheap, there should be little post-treatment discomfort, return to normal activities should be quick, the percentage of complications should be low, the recurrence rate should be minimal and the resulting toe should be cosmetically acceptable

Several surgical procedures and chemical ablation of the nail matrix have been described, and well documented studies have been reported[1–5]. Conservative treatment is frequently associated with a high recurrence rate and a high percentage of defaulters[6]. However, conservative treatment of the ingrowing toenail can succeed, even in advanced cases[7], but reports of such treatment are rare.

We have studied a combination of conservative measures in the light of the above criteria.

Patients and methods

A prospective study was performed, according to a fixed protocol, on 105 consecutive patients with ingrowing toenails. The patients were treated by one of a group of ten general practitioners or on an out-patient basis by one of the authors (J A M.R.). Only patients with ingrowing nails of the big toe were included in the study. Patients with onychogryphosis, onychomycosis and obvious orthopaedic foot disorders, such as hallux valgus and hammer toes were excluded from the study.

After diagnosis and obtaining informed consent the toe was cleansed. Any spur of the nail edge was removed. The middle one-third of the nail (10–15 mm) was thinned by filing the upper surface until the matrix beneath it could be seen. The offending nail edge was lifted out of the nail fold and debris was removed from under it. Granulation tissue was reduced by silver nitrate application. A small piece of cotton wool, soaked in alcohol 60 per cent, was packed firmly under the nail edge (*Figure 1*). The patients were instructed to renew the cotton wool once a day They were also given advice on footwear and foot hygiene, especially nail trimming They were told to resume normal activities as soon as possible

The patients were asked to return for assessment after 2 weeks. Any residual granulation tissue was treated with silver nitrate. If signs of inflammation were still present the patients were instructed to continue packing They were told to restart packing if the symptoms and signs of inflammation returned All patients were asked to note the first day on which they had no more symptoms and the day on which they resumed normal activities. They were asked to file the nail shortly before each check visit. All patients were seen by one person (J A.M.R) at 1, 12 and 24 months after presentation to assess correct nail filing and symptoms and signs of recurrence. At 4 and 8 months they were seen by their general practitioner or by J.A.M R. Indications for abandoning the conservative approach were persistent disabling pain, the development of cellulitis, and by request of the patient.

Patients were divided into three groups, according to the stage of ingrowing toenail at presentation. For this purpose the stages described by Heifetz[8] and Mogensen[9] were used The first stage is characterized by pain, reddening and slight swelling of the nail wall. In the second stage, swelling, pain and redness are accompanied by infection and suppuration. In the third stage, formation of granulation tissue and hypertrophy of the nail wall occur and all characteristics of the second stage are more markedly present. Patients were considered cured at the time they had no symptoms and no signs of inflammation

Results

We treated 105 patients, 65 male patients and 40 female patients. The mean age at presentation was 21·9 years (range 12–79 years); 78 per cent were under 30 years old Both feet were simultaneously affected in 14 patients. The lateral side of the nail was involved in 65 cases, and the medial side in 35 cases. In the remaining cases, both sides were affected. As regards cause, a history of improper nail trimming was identified in 82 cases, injury to the toe in 65 cases, tight footwear in 40 cases, and hyperhidrosis in 67 cases Hyperhidrosis almost always occurred in combination with the wearing of tight synthetic socks. Fourteen patients had been previously treated by nail avulsion and 16 by wedge resection; 23 patients had been treated by a chiropodist.

Twenty patients presented with stage I ingrowing toenails, 47 with stage II and 52 with stage III Sex and age were similarly distributed between the three groups. The mean duration of symptoms was 9 weeks for stage I, 11 weeks for stage II and almost 14 weeks for stage III The distribution of all cases over the three stages, cured cases and cases which were treated

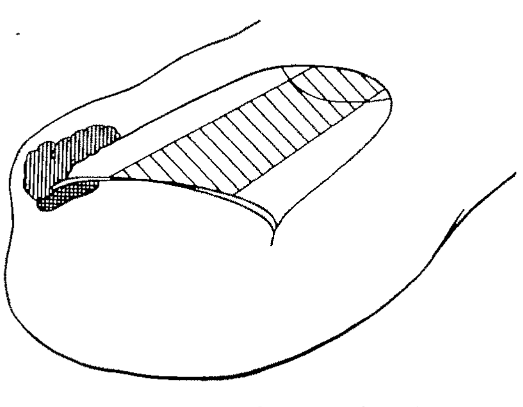

Figure 1 *Ingrowing toenail treated by filing the nail, packing the nail fold and reducing granulation tissue by the application of silver nitrate*

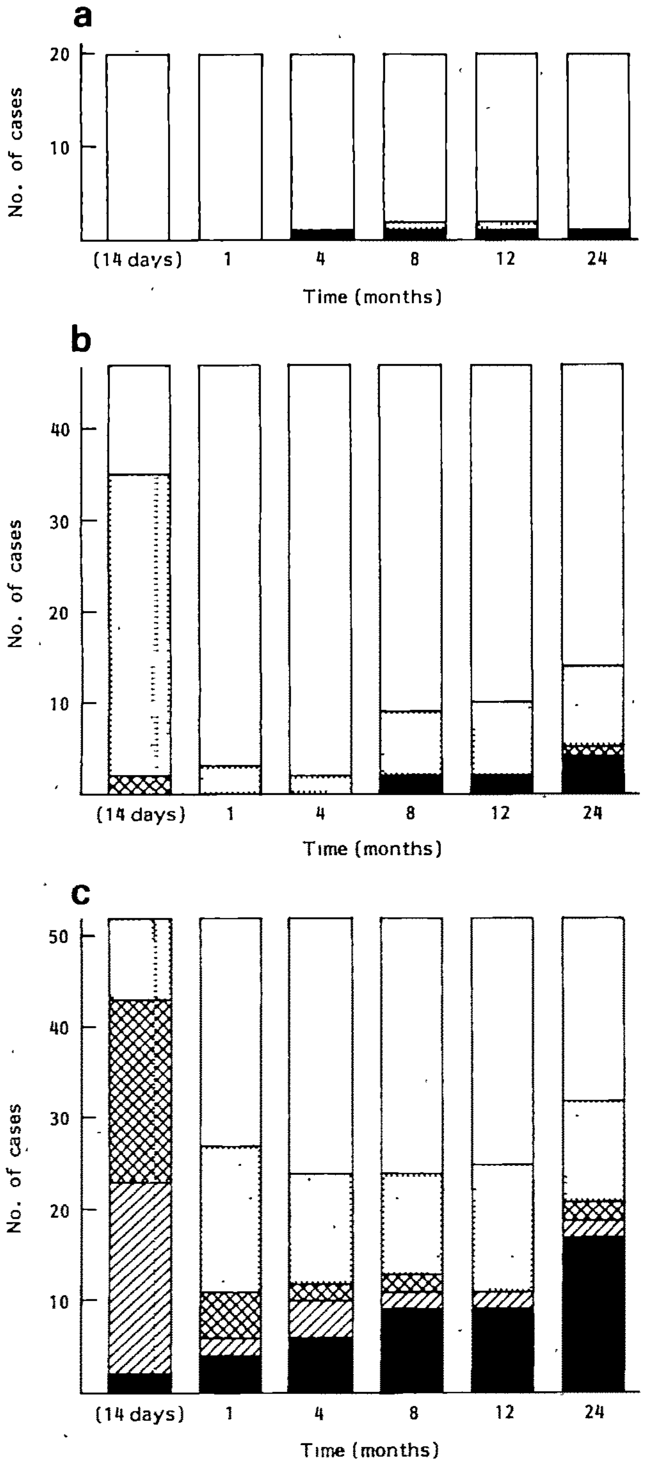

Figure 2 *Outcome at different intervals after presentation in* **a** *20 cases with stage I,* **b** *47 cases with stage II and* **c** *52 cases with stage III ingrowing toenails* □, *cured,* ▨, *stage I,* ▩, *stage II,* ■ *stage III,* ■, *surgical treatment*

surgically at different intervals after presentation, is shown in *Figure 2*.

Of the cases presenting in stage I, all were cured within 14 days. In only two did symptoms and signs of stage I ingrowing toenails recur and these patients were treated successfully with the same regimen. One patient, initially presenting in stage I, had complaints 2 months after presentation without any sign of inflammation. She insisted on surgical treatment. After segmental matrix excision and phenolization, she complained of the cosmetic result, but had no pain.

The cases with stage II ingrowing toenails were, for the greater part (44 cases), cured within 4 months but, between 4 and 24 months, symptoms and signs recurred in 18 cases, of which only four were treated successfully with conservative measures.

About one-half of the patients with stage III ingrowing toenails continued to complain and, as a result, 12 asked for surgical treatment. In contrast, two patients with stage III (nail wall hypertrophy) did not improve for 24 months but refused surgical therapy. Of the 28 patients with stage III who were cured after 4 months, nine developed symptoms and signs which could be treated conservatively in only one case. Two stage III patients had to be treated surgically within 2 weeks from presentation because of cellulitis. Nine of 30 cases treated surgically in the past presented with stage II; of these seven could be cured, but in four cases there was a recurrence. Of the other 21 cases only two could be temporarily cured.

Table 1 shows the pain duration and the time taken to return to normal activities for those patients in each group who were cured. Only 15 patients (11 women) had complaints with regard to the cosmetic result Most men did not seem to care very much and women used nail varnish as camouflage An inconvenience was rupture of the nail so that socks could easily get snagged. This happened 31 times.

At 53 of all check visits, patients had to be reinstructed because they had not filed the nail correctly. Packing the nail fold was never a problem.

We calculated that the cost of materials, such as files, cotton wool, and alcohol, was less than 5 pounds sterling. For stage I ingrowing toenails, two or three check visits were necessary. For stage II patients, at least three visits were required. Half the patients with stage III lesions had to be seen at least six times.

Discussion

In the past, nail avulsion, wedge resection, total matrix ablation and other surgical treatments of ingrowing toenails have been associated with high recurrence rates, considerable postoperative pain and poor cosmetic results[1,2]. More recent studies have shown that, with segmental matrix excision, segmental phenolization, and wedge resection in combination with segmental phenolization, far more acceptable results can be achieved[3–5]. For the results of conservative treatment, most authors have referred to the article by Lloyd-Davies and Brill published in 1963[6]. These authors treated 100 consecutive patients in their toe clinic by warm soaks, cotton wool packing beneath the nail and in nail grooves, removing granulations by silver nitrate application, and extensive hygiene instruction. Some of their patients had been treated previously by total nail avulsion. According to their article, 33 per cent of patients were discharged cured after 2 years, and 27 per cent were still under treatment. Forty per cent had defaulted[6]. However, a success rate of 79 per cent for conservative management has been reported even in advanced cases, although follow-up has only amounted to 6 months[7]

Our study shows that conservative treatment of ingrowing toenails is simple but time consuming. It requires a high degree of co-operation from the patient and perseverance on the part of the doctor. Because of the intensive support necessary it is not a cheap method of treatment. The cosmetic result, post-treatment pain duration and time taken to return to normal

Table 1 *Mean postoperative pain duration and mean time taken to return to normal activities in 93 cases of successfully treated ingrowing toenail*

Stage	No of patients cured	Pain duration (days)	Time to resumption of normal activities (days)
I	20	2	1
II	45	5	5
III	28	17	15

activities are acceptable For stage I ingrowing toenails the combination of conservative measures studied was shown to be successful. In cases of stage II ingrowing nails, success can also be achieved but recurrences are frequent in the long term (30 per cent). The failure rate is much higher in advanced cases (62 per cent in stage III), especially in patients who have previously been treated surgically. These patients can only be cured at the cost of great effort on the part of both patient and doctor. However, conservative treatment must be considered before proceeding to surgery for patients with stage III ingrowing toenails who suffer from vascular disease or diabetes.

We conclude from our data that stage I ingrowing toenails can be successfully treated by packing the nail fold with cotton wool after thinning the nail. Cure of stage II lesions can only be achieved by these measures if co-operation from the patient is guaranteed. In stage III, a non-conservative approach seems to be indicated.

Intraoperative colonic irrigation in the treatment of acute sigmoid volvulus

M. Gurel, B. Alic, B. Bac, C. Keles, Y. Akgun and S. Boylu

Department of Surgery, Dicle University Medical School, P.K 402 Diyarbakir, Turkey
Correspondence to: Dr M. Gurel

The surgical treatment of acute left colonic obstruction continues to be a controversial subject[1]. Since the introduction of intraoperative colonic irrigation[2], resection and primary analstomosis has become an acceptable method in the treatment of obstructing carcinoma of the left colon[3].

Acute volvulus of the sigmoid colon is a rare cause of intestinal obstruction in western countries, seen mostly in mental institutions and in the very elderly, and accounting for only 3–5 per cent of all cases of mechanical obstruction[4–6]. In Turkey, particularly in the south-east region, cases of sigmoid colon volvulus are seen much more frequently and cause 25 per cent of all cases of intestinal obstruction and the majority of cases of left colon obstruction treated in our department.

The purpose of this study was to determine whether intraoperative colonic irrigation could be used in the definitive, one-stage surgical treatment of acute sigmoid volvulus by reducing the incidence of anastomotic disruption after emergency colonic resection with primary anastomosis.

Patients and methods

During the 1-year period between December 1987 and December 1988, 11 patients with acute sigmoid volvulus were admitted to our department and offered surgical treatment. Two patients refused and were managed by sigmoidoscopic reduction. These patients were later discharged without consenting to further therapy

The remaining nine patients were managed by intraoperative colonic irrigation, sigmoid resection and primary anastomosis covered by a tube caecostomy.

The patients ranged in age from 26 to 85 years with a mean age of 57 years All were men and none had a previous history of mental disease. Three patients had experienced acute sigmoid volvulus previously, and one patient had had sigmoidoscopic reduction six times. Duration of symptoms was 1–7 days with a mean (s.d.) of 3·2(2·2) days. All patients complained of cessation of defaecation, seven had abdominal pain, and three had nausea and vomiting Physical examination revealed abdominal distension in all patients. Two patients with muscle guarding proved to have a gangrenous sigmoid colon at laparotomy.

Plain abdominal radiographs obtained in all patients showed evidence of sigmoid volvulus. Routine biochemical studies were carried out. The plasma total protein level, determined in seven patients, was found to be uniformly decreased with a mean (s.d.) value of 4·9(0·8) g/dl

A left paramedian or transverse incision was used in all cases The colon was manually untwisted while care was taken not to allow faecal material to enter the empty colon distal to the volvulus The distal margin of the resection was determined and the colon was divided between two clamps

The mesocolon was clamped and resected close to the colon, and the sigmoid colon was brought out through the laparotomy wound. A 20–22 Fr gauge Foley catheter was inserted into the caecum either through a caecostomy or the appendix stump after a purse-string suture had been applied The colon was rapidly washed out with 3–5 litres of warm saline until the effluvium was clear. A three-lumen Foley catheter (*Figure 1*) used in the last four cases afforded a higher flow rate and the irrigation time was shortened.

The sigmoid colon was then divided proximally, completing the resection A two-layer colocolic primary anastomosis was performed The irrigating catheter was brought out through a separate right lower stab wound as a tube caecostomy (*Figure 2*). After an additional purse-string suture had been placed, the caecum was secured to the peritoneum with four seromuscular sutures.

Anal dilatation was routinely employed while the patient was still under anaesthesia, and a rectal tube was inserted (*Figure 2*).

The tube caecostomy was irrigated during the first 7 days to avoid plugging and was clamped 7–11 days after operation The catheter was removed in the ward 24–48 h later

Results

No mechanical problems involving the tube caecostomy were observed; 100–500 ml of fluid were drained each day

Three patients had a total of four postoperative complications. One wound infection and two wound dehiscences were

0007–1323/89/090957–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

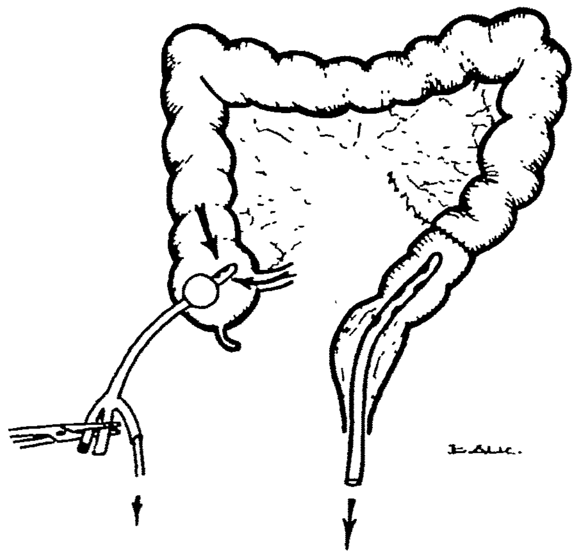

Figure 2 *After the resection the irrigating catheter is converted to a tube caecostomy and a rectal tube is placed*

observed. An anastomotic leak developed in one of the patients with wound dehiscence and was managed conservatively. This patient was later discharged with a low-grade intermittent faecal fistula (1–2 ml per day) having refused further surgical treatment.

There was no operative mortality.

Discussion

A dilemma is encountered when planning the emergency surgical treatment of acute sigmoid volvulus.

Simple operative untwisting, whether accompanied by additional fixation techniques such as sigmoidopexy or not, affords only temporary relief and is associated with a high recurrence rate[7,8] unless followed by definitive surgical treatment entailing a second operation. Resection and anastomosis, while achieving complete cure, is associated with prohibitively high morbidity and mortality rates arising from operating on an unprepared colon in the emergency setting[7,8]. Resection and end-colostomy or primary anastomosis with a proximal colostomy may be safe alternatives[6] but a further operation, with its attendant risks, for the closure of the colostomy is mandatory.

Non-operative therapy consisting of sigmoidoscopic reduction may seem to be the ideal initial treatment, relieving the obstruction and allowing the colon to be prepared for safe elective resection. While high success rates have been reported, recurrences are common[5–7,9]. Another drawback that we encountered was the unwillingness of patients, relieved of their symptoms, to undergo elective surgery. Even though the high risk of recurrence is stressed most patients refuse surgery, later returning to start the whole process again. Furthermore non-operative treatment is impossible in the presence of gangrene and may even increase the risk of perforation.

Intraoperative colonic irrigation followed by resection and primary anastomosis with the irrigating catheter converted to a caecostomy affords satisfactory surgical treatment in acute sigmoid volvulus. It achieves complete cure in one stage and no further treatment is required. This technique can be used in all cases of sigmoid volvulus. The presence of gangrene does not require any modification.

The only serious morbidity associated with this procedure was in the patient with a low volume faecal fistula. The poor general and nutritional status of our patients, as evidenced by the low plasma protein levels, may have contributed to this complication and to the two wound dehiscences. We believe that the presence of a caecostomy acting as a proximal covering colostomy prevented the development of more serious complications.

Double-lumen Foley catheters, in addition to speeding up colonic irrigation, allowed one lumen to be used for irrigation and the other for drainage during the postoperative period, preventing the formation of plugs within the caecostomy tube.

We conclude that this technique may be used in patients suspected of having a gangrenous colon and in those in whom sigmoidoscopic untwisting fails. Patients with multiple episodes of volvulus may also be considered However, sigmoidoscopic reduction followed by elective resection is still the treatment of choice when possible.

Results of external sphincter repair in Crohn's disease

A. Scott, P. R. Hawley and R. K. S. Phillips

St. Mark's Hospital and Professorial Surgical Unit, St. Bartholomew's Hospital, London, UK

Correspondence to:
Mr A. D. Scott, Professorial Surgical Unit, St. Bartholomew's Hospital, West Smithfield, London EC1A 7BE, UK

The results of anal sphincter repair in a group of six patients with anorectal Crohn's disease are reported. All patients had previously undergone anal surgery which was followed by faecal incontinence in five. The sixth patient became incontinent following obstetric injury. Of the six patients, five are completely continent and one has a permanent stoma (follow-up from 18 months to 16 years, mean 7·8 years). Anal sphincter repair in this highly selected group of patients with Crohn's disease has not been complicated by wound breakdown or fistula formation, and has given good results.

Keywords: Crohn's disease, anus, faecal incontinence

Despite a conservative approach to the surgical treatment of perianal disease[1,2] patients with Crohn's disease are susceptible to anal sphincter damage as a result of perianal sepsis and the consequences of fistula surgery. Many patients can cope with a weak sphincter provided the colon and ileocaecal valve are preserved and their stools are formed, but should they suffer diarrhoea then incontinence is almost inevitable. Relative incontinence can be an indication for a more radical procedure on account of the concern over incontinence with a conservative operation.

Sphincter repair normally gives good results. For example, Motson[3] found in Sir Alan Parks' series that 78 per cent of patients achieved a Grade 1 result (continent of solid and liquid stool) and in a postal survey he found that nine other centres had achieved similar results. Other authors[4,5] have reported comparable success.

The fear of failure has made surgeons reluctant to consider sphincter repair in Crohn's disease[6]. In order to assess whether sphincter repair in Crohn's disease is practicable, seven patients have been assessed retrospectively.

Patients and methods

Between October 1971 and June 1986 seven patients with Crohn's disease underwent sphincter repair at St. Mark's Hospital. Of these, one patient was lost to follow-up 6 months postoperatively and has therefore been excluded from the study (*Table 1*). During the same period a proctectomy or proctocolectomy for Crohn's disease was performed in 152 patients. Anal lesions were the main indication for surgery in 35 (23 per cent) patients and a contributing factor in 66 (43 per cent), whereas in 51 (34 per cent) patients anal disease was not an indication for surgery.

All six patients had undergone previous perianal surgery, three for abscess and three for fistula. In five of the six patients the previous perianal surgery had caused the sphincter injury and consequent incontinence. The other patient had excision of oedematous skin tags following which continence was normal. Seven years later she suffered an obstetric injury and became faecally incontinent.

The time interval between the original diagnosis of Crohn's disease and sphincter repair in five patients ranged from 6 months to 8 years, while in one patient from abroad this time interval could not be ascertained.

All five women had been diagnosed histologically as having intestinal Crohn's disease: four had ileocolic disease and in one only the large bowel was affected. All five patients at some time underwent intestinal resection for Crohn's disease: three had a right hemicolectomy and two had a subtotal colectomy with ileosigmoid anastomosis. Of the hemicolectomies, one (patient No. 5; *Table 1*) was performed at the same time as the sphincter repair together with a rectopexy. The indication for rectopexy in this patient was a full thickness rectal prolapse on straining; the mesorectum was sutured to the sacral promontory but no mesh was inserted. Sphinter repair was performed before resection in two of the other patients and after resection in a further two.

All six patients were diagnosed clinically as having perianal Crohn's disease. One patient (No 6) had active disease with oedematous skin tags, abscess formation and a rectovaginal fistula and the diagnosis was confirmed histologically. In two patients (Nos. 3 and 4) there was quiescent disease with histological confirmation and in the remaining three patients the anal disease was quiescent and histological confirmation of anal disease was not obtained, although they were all known to have intestinal Crohn's disease.

Details of preoperative anorectal physiology were available in three of the six patients and confirmed an abnormal external sphincter with voluntary squeeze pressures of 35 cmH_2O or less. No postoperative studies of anorectal physiology have been performed.

A standard overlap type of repair was used in each case[7]. Prolene® (Ethicon Ltd., Edinburgh, UK) was used for the repair in one patient, nylon in another and stainless steel wire in the other four (*Table* 1). In one patient (No. 6) repair included closure of a rectovaginal fistula. In all but one of the six patients a proximal stoma was either present before operation or constructed as part of the operation (one terminal ileostomy, one loop ileostomy, one end colostomy and two loop colostomies).

Results

In one patient the deep part of the sphincter repair broke down and had to be repaired 16 days after operation. All five patients who had a stoma subsequently had it closed between 2 and 20 months postoperatively.

Of the six patients, one remained incontinent after operation and required a permanent colostomy. The remaining five patients are fully continent of flatus, liquid stool and solid stool (follow-up varies from 18 months to 16 years, mean 7·8 years).

The patient who remains incontinent has had no recurrence of intestinal or perianal disease. Of the other five patients, two (Nos. 1 and 4) still have signs of perianal Crohn's disease and four have had recurrence of intestinal disease.

Discussion

Perianal disease is a common feature of Crohn's disease[8,9] and a frequent indication for surgery[10]. However, it is hard to define anal involvement in Crohn's disease. Multiple fistulae associated with purulent discharge and abscesses clearly constitute active disease, and one of the patients in this survey who achieved a Grade 1 result was in this situation. However, small asymptomatic skin tags obviously do not represent active disease; patients with this clinical picture are expected to fare better after any sort of anorectal surgery. Indeed, if skin tags are included then anal lesions may be found in as many as 80 per cent of patients[11], but symptomatic anal disease (excluding skin tags) has been described in only a third (49 of 151 successive patients[12]) treated for Crohn's disease. In addition, fistula *in ano* may be incidental to intestinal Crohn's disease. Attitudes to sphincter surgery in anorectal Crohn's disease have been mixed[13,14] but, at the very least, the results

Period of follow-up (years)	16	4	15	2·5	1·5	1·5

Patient No 2 died of a pulmonary embolus 2 years after colectomy; IC, ileocolic disease, C, colonic disease; PA, perianal disease only, RHC, right hemicolectomy; STC, subtotal colectomy; S, stainless steel; N, nylon; P, Prolene

presented here indicate that an incidental diagnosis of Crohn's disease should not preclude an attempt at anal sphincter repair.

A covering stoma is much less frequently used in conventional sphincter repair than previously but it seems a reasonable precaution when operating in Crohn's disease. The only patient who did not have a covering stoma had a poor result.

In conclusion, this highly selected group of patients with Crohn's disease who have undergone sphincter repair have not suffered complications of wound breakdown or fistula formation. Their functional results have been good. In the light of these results, which are similar to those achieved in patients without inflammatory bowel disease, it may be appropriate to consider sphincter repair in patients with mild or quiescent Crohn's disease when the alternative is proctocolectomy

Totally stapled abdominal restorative proctocolectomy

A technique of totally stapled abdominal restorative proctocolectomy is reported in 20 consecutive patients using a 20 × 20 cm J pouch and a stapled ileoanal anastomosis. The stapled ileoanal anastomosis had to be abandoned in three patients because of attempted mucosectomy in one and megarectum in two. One patient receiving steroids had a covering ileostomy. The remaining 16 patients had a totally stapled procedure without a covering ileostomy. Three patients developed serious postoperative morbidity but they were the only patients receiving steroids at the time of the operation. Of the remaining 13 patients none developed serious complications, the median hospital stay was 14 days and the median operating time was 150 min. The operation may be a technical advance particularly in allowing pouch construction without ileostomy in fit patients who are not receiving steroids at the time of operation.

Restorative proctocolectomy with ileal reservoir and ileoanal anastomosis has now become an alternative to conventional proctocolectomy and end ileostomy for patients with ulcerative colitis, familial adenomatous polyposis and some forms of functional bowel disorder[1].

The aim of restorative proctocolectomy is to eradicate the entire disease-bearing colorectal mucosa while preserving anal sphincter function[2]. The high frequency of defaecation and episodic incontinence associated with straight ileoanal anastomosis has now largely been overcome by providing an ileal reservoir[3,4].

There is evidence of impaired sphincter function following anal mucosectomy during the operation of restorative proctocolectomy which is probably associated with prolonged anal retraction[5]. Evidence from some centres suggests that ileoanal anastomosis to the upper anal canal is associated with improved functional results when compared with conventional endoanal anastomosis to the dentate line[6]. This may be due partly to the avoidance of anal sphincter damage and preservation of the anal transition zone. A prospective randomized trial has indicated that the clinical result of a stapled J pouch was indistinguishable from the more time-consuming but theoretically larger W pouch[7].

If restorative proctocolectomy is to become widely adopted it is important that it should be a procedure that can be safely executed with minimal morbidity. The development of stapling instruments has allowed the operation to be accomplished by an experienced colorectal surgeon who has sufficient experience of stapling techniques[8,9]. Our own experience suggests that the totally stapled restorative proctocolectomy is associated with a lower morbidity than the conventional hand-sutured pouch construction and ileoanal anastomosis[10].

In 1988, 20 consecutive restorative proctocolectomies have been performed and in all of these operations a totally stapled procedure has been attempted. The operations were performed by a single surgeon (M.R.B.K.) with the help of one assistant and a scrub nurse. No special pelvic retractors were used.

Patients and methods

After a standard bowel preparation the patient is anaesthetized, catheterized and placed in the Lloyd-Davies position.

A long midline incision is used and the colectomy is performed in the usual manner with preservation of the ileocolic artery. The ileum is transected at the ileocaecal valve using the TA30®, GIA50® (US Surgical Corporation and Auto Suture UK, Ascot, UK) or proximate PCL50® (Ethicon Ltd., Edinburgh, UK) stapler. Unlike the hand-sutured ileoanal anastomosis, the duodenojejunal flexure and the origin of the superior mesenteric artery rarely need to be mobilized. The rectal dissection used by this surgeon involves radical mesorectal excision as in proctectomy for malignant disease. In this way there is no tissue in the posterior aspect of the pelvis to limit access to the upper anal canal. The posterior dissection proceeds immediately behind the superior haemorrhoidal artery, taking the mesorectum down to its limit at the anorectal junction. There should be no fear of damage to the pelvic nerve as these can be readily visualized crossing the pelvic brim. Damage to the autonomic supply to the prostate, seminal vesicles, bladder and vagina will be avoided provided the anterior plane lies well behind Denonvilliers' fascia. The rectum and the upper half of the anal canal must be completely mobilized. This is only possible by dividing Waldeyer's fascia between the rectum and the puborectalis sling. At this stage it is helpful to place a clamp across the upper anal canal at the proposed anastomosis site and to examine the anal canal digitally to ensure that at least 2 cm of anal canal is preserved above the dentate line.

A TA30 stapler is then applied across the upper anal canal at the desired distance from the dentate line (*Figure 1*) and the instrument is fired. The anal canal is transected above the staples and the rectum

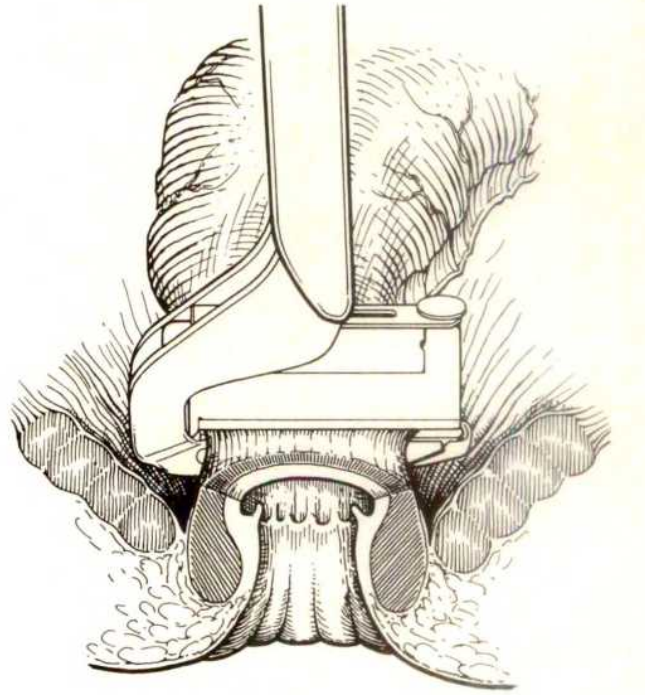

Figure 1 *Stapled transection of the upper anal canal using the TA30® stapler*

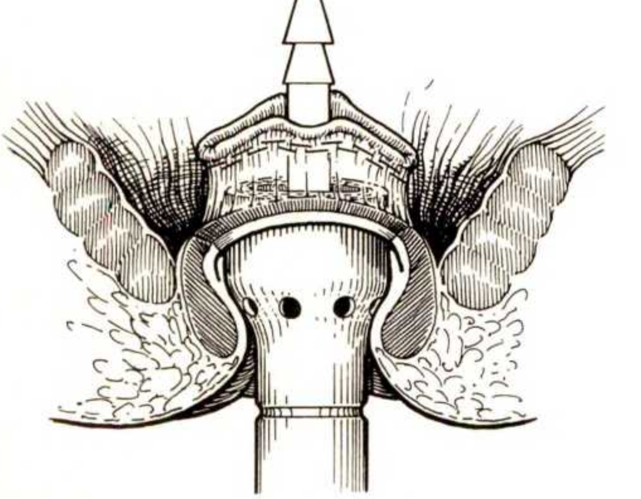

Figure 3 *Insertion of the central pin attached to the instrument head through the staple line of the previously transected anal canal*

removed. A double-limb J pouch 20 × 20 cm is measured and tested for length by placing a Duval clamp across the proposed apex of the pouch to ensure that it can be approximated to the stapled anal transection line. Using this technique the vessels in the small bowel mesentery have never needed to be divided. An enterotomy is made in the apex of the proposed pouch and the two limbs approximated by three stay sutures. The limbs of the pouch are stapled together using either two applications of the long GIA90® (US Surgical Corporation and Auto Suture UK; *Figure 2*) or three or four applications of the GIA50 or proximate PCL50 stapler. These instruments produce a double staple side-to-side anastomosis. To avoid multiple enterotomies the bowel is telescoped over the reloaded stapler, advancing beyond the previous staple line until both limbs have been anastomosed.

A purse-string 0 Prolene® (Ethicon Ltd., Edinburgh, UK) suture is placed around the enterotomy in the apex of the pouch. A 30 Fr Foley catheter is then inserted through the distal enterotomy and a non-crushing clamp is applied to the proximal small bowel. Saline 300–400 ml is introduced into the pouch to identify any leaks in the anterior and posterior staple line. This procedure also allows the evacuation of clot from the stapled pouch.

The ileoanal anastomosis is performed using the premium EEA® (US Surgical Corporation and Auto Suture UK) stapling instrument. The anvil of the circular stapler is removed and replaced by a pointed central pin. The central pin is retracted inside the instrument. The shoulders of the head are gently inserted into the short anal stump against the transected staple line. The central pin is then advanced while the abdominal surgeon checks by palpation and vision that the pin penetrates the centre of the anal staple line. The perineal operator then pushes the pin through the staple line aided by counter-pressure from above (*Figure 3*). After fully advancing the shaft, the pin is removed from the stapler head. The anvil of the stapler is inserted into the apex of the pouch through the previously inserted Prolene purse-string suture which is then tied around the anvil pin in the groove (*Figure 4*). The anvil pin can be snapped into the hollow end of the main shaft (*Figure 5*). The circular stapler is then closed until it is in the firing position on the gauge, the safety catch is released and the instrument is fired. Two concentric circles of staples are applied and a hole is cut within the inner staples. The tissue includes a short cylinder of anal canal and the apex of the pouch. The stapling instrument is unwound by two and a half counter-clockwise turns. The entire instrument is then rotated to ensure that the blade has completely divided both ends of the bowel and the instrument is then gently withdrawn through the anus by the abdominal surgeon who applies gentle traction on the pouch to disengage the stapling device.

The completeness of the two 'doughnut' rings is checked and the anastomosis is palpated through the anus to ensure that it is intact. The pelvis is then filled with saline, a non-crushing clamp is applied across the proximal small intestine and the absence of air leaks is verified by inflation of the pouch per anus using a 50 ml syringe. Provided there are two complete rings, no air leaks and the staple line appears to be intact on palpation, no covering ileostomy is raised.

Two closed suction drains are placed in the pelvis for 48–72 h. A 30 Fr latex catheter is inserted through the anal anastomosis into the pouch and sutured to the perianal skin. This catheter is used to irrigate the pouch with 50 ml saline 4-hourly for the first 3–4 days to remove haematomas. Irrigation stops when small bowel contents start issuing

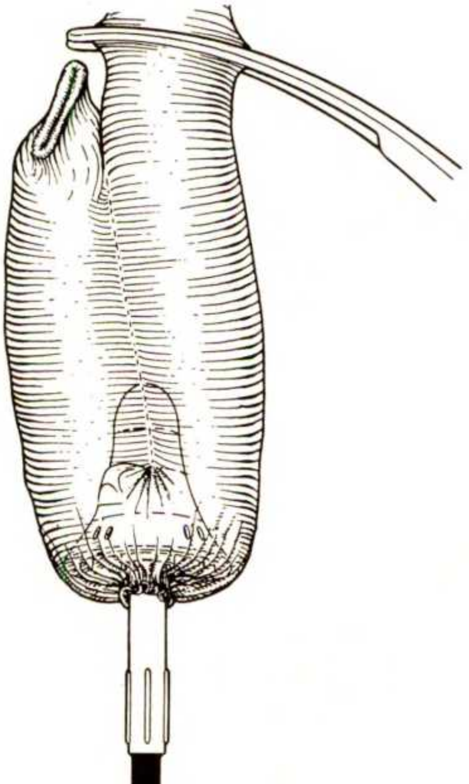

Figure 4 *Anvil secured in the J pouch by a purse-string suture at its base*

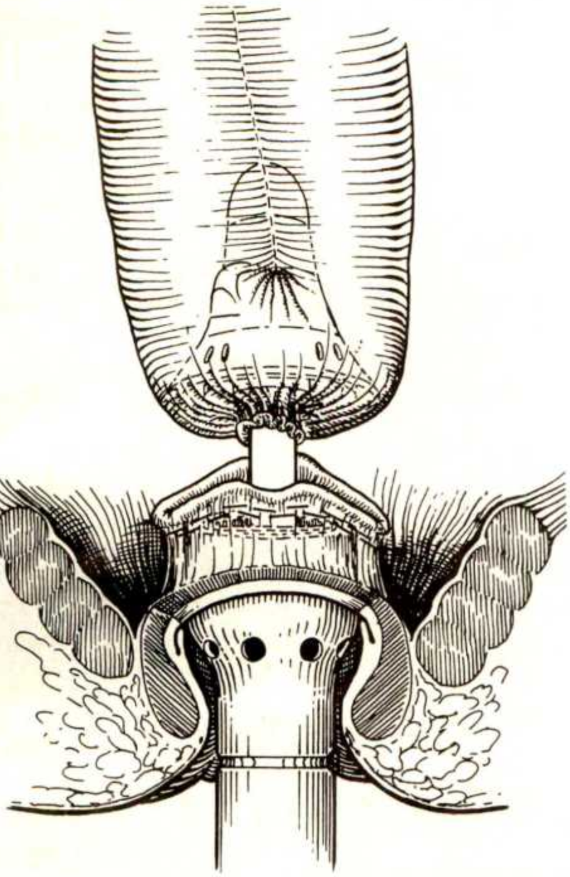

Figure 5 *Advancement of the anvil pin into the hollow end of the main instrument, thereby joining the J pouch to the anal canal*

from the catheter. The catheter then acts as a perineal ileostomy and is usually removed between 7 and 10 days after the operation. Most patients are able to be discharged from hospital 4–5 days later.

Results

Totally stapled restorative proctocolectomy has now been used in 20 consecutive patients since January 1988 (nine male patients, median age 30 years (range 16–60 years)). Fourteen patients had a diagnosis of ulcerative colitis, three had operations for familial adenomatous polyposis and three male patients had a megarectum due to aganglionosis. In 12 patients total colectomy, rectal excision and pouch construction were performed as a one-stage procedure, the remaining eight patients had had a previous colectomy, ileostomy and the rectal stump had been oversewn.

The median operating time was 155 min (range 120–220 min) and the median duration of hospital stay was 14 days (range 12–104 days). There were three operative technical failures. In the first patient an attempt was made to perform an abdominal mucosectomy; subsequent attempted transection of the anal canal was incomplete. In the other two patients, both of whom had a megarectum, the bowel was too dilated to allow the TA30 stapling instrument to be inserted around the mid-anal canal. All of these patients underwent a sutured ileoanal anastomosis which was protected by a loop ileostomy. Two of these patients have had uncomplicated ileostomy closures (2 and 3 months postoperatively) while the other patient awaits closure.

Of the remaining 17 patients only one had a covering ileostomy. This patient was receiving steroid therapy at the time of operation. Pouch construction was technically difficult and there was some persistent bleeding in the pelvis, hence a loop ileostomy was raised. The patient developed pelvic sepsis thought to be due to a pelvic haematoma. Despite this the loop ileostomy was subsequently closed without complication (hospital stay 22 days).

Sixteen patients had a totally stapled restorative proctocolectomy without a covering ileostomy. In three patients there was major morbidity. All three patients were receiving steroid therapy at the time of the operation. One patient developed Gram-negative shock due to peritonitis which was not evident clinically. There was no radiological evidence of leakage and air insufflation of the pouch at the time of laparotomy 7 days after the initial operation failed to detect leakage. Despite this, the proximal bowel was transected with construction of an end ileostomy and a mucous fistula (hospital stay 26 days). A second patient developed a pelvic haematoma and radiological evidence of leakage from the transected ileum. The ileoanal anastomosis was intact. The patient underwent construction of an end ileostomy and a mucous fistula 21 days after operation (hospital stay 37 days). One further patient receiving steroids at the time of operation, who has already been reported[11], developed an intussusception of the afferent limb resulting in proximal infarction of the pouch necessitating excision 5 days after the original operation (hospital stay 104 days).

Of the remaining 13 patients who had a totally stapled procedure without a covering ileostomy, only two developed minor complications: both were wound infections at the site of the previous ileostomy. The median hospital stay of these patients was 14 days (range 11–17 days). All of these patients at the time of discharge from hospital were fully continent during the day but two reported intermittent soiling at night necessitating the wearing of a pad. At the time of discharge the median frequency of defaecation was 6 (range 5–9) during the day and 1 (range 0–3) at night. Although the stool was generally fluid, all patients could defer defaecation for at least 30 min and all patients were able to discriminate between liquid stool and flatus.

Eight of these 13 patients who did not have a loop ileostomy have now been assessed at least 3 months after discharge from hospital. All remain continent by day but one patient still complains of soiling at night. The median frequency of defaecation is 5 times in the day (range 4–8) and once at night (range 0–3). All patients are able to defer defaecation for more than 1 h and seven of the eight now pass semisolid stools.

Discussion

The totally stapled pouch technique offers major advantages in terms of operating time and avoidance of a proximal ileostomy. In patients who have no major morbidity, the longest hospital stay was only 17 days and one patient was discharged 11 days after operation. A second admission was avoided and the known morbidity attending closure of a loop ileostomy was entirely eliminated[12]. The cost of the staples for this procedure is 435 pounds sterling, but the financial benefit of avoiding a second admission, usually for 8–10 days, is clearly outweighed by this reduction in total hospital stay when proximal ileostomy is avoided. Another potential benefit over other techniques described in the literature[8,9] is the use of the single distal enterotomy for pouch construction and the long-limbed GIA90 instrument. The distal enterotomy technique minimizes the risk of leakage when compared with multiple enterotomies for a stapled pouch construction[10,12].

In common with other authors[6,9] the mucosectomy has been abandoned as the ileoanal anastomosis is placed 1 cm above the dentate line. The worry in colitic patients of persistent colitis and of carcinoma in the small 1 cm cylinder of at-risk mucosa has not been borne out by clinical follow-up in patients where the anal transition zone has been deliberately preserved[13–15]. However, follow-up of these patients is short. In a recent cohort study of cancer risk in ulcerative colitis, 261 patients from Birmingham presented with ulcerative colitis between 1945 and 1975[13]. Of 2500 patient-at-risk years of developing malignancy, three rectal cancers presented. We have analysed these three patients and no tumour presented in the distal 3 cm of the rectal mucosa. Clearly the long-term cancer risk cannot be ignored[16]; however, this short cylinder of mucosa is easily accessible to the rigid sigmoidoscope and the examining index finger[6]. In one patient the retained mucosa has bled postoperatively, but this settled spontaneously. Biopsy did not reveal features of active colitis.

Using the described technique in which the mid-anal canal is stapled, the internal anal sphincter is partially excised. Nevertheless, no patient was incontinent, and anal pressures have been well preserved.

There were no episodes of small bowel obstruction. Previous studies identify adhesive obstruction as an important cause of morbidity but this may be partly related to a proximal ileostomy and its subsequent closure[12,15].

A number of important lessons emerge from this small consecutive series. The staple transection of the anus in patients with gross megarectum for aganglionosis is technically difficult as these patients are usually male. It is probably wiser under these circumstances to perform a conventional sutured ileoanal anastomosis which is covered by a loop ileostomy. The operation of one-stage totally stapled restorative proctocolectomy without a covering ileostomy is unwise in patients receiving steroid therapy. All three patients in this category developed major complications, one necessitating pouch excision and the other two requiring a difficult laparotomy and proximal intestinal diversion.

If, on the other hand, the patient is no longer taking steroids and there are no technical difficulties, the totally stapled restorative proctocolectomy is a major advance, both in the reduction of operating time and the avoidance of a proximal stoma. The anus must be transected well below the anorectal junction, preferably 2 cm from the dentate line, and no attempt should be made to perform a mucosectomy. If technical difficulties arise the ileoanal anastomosis may have to be hand-sutured using an intra-anal technique. Hence experience with these alternative techniques is essential before embarking on this modification of the operation.

A series of 908 cases of colonic carcinoma has been analysed to elucidate reasons for the poor prognosis in obstructing colonic cancer. Complete obstruction was present in 148 cases (16·3 per cent), 280 cases (30·8 per cent) had partial obstruction and 480 (52·8 per cent) presented without obstruction. There were fewer Dukes' A tumours in those with complete obstruction ($P<0{\cdot}005$) *and greater numbers of advanced tumours* ($P<0{\cdot}0005$) *compared with those without obstruction. This is reflected in a lower curative resection rate of 50·7 per cent in those with obstruction compared with 70·6 per cent in those without obstruction* ($P<0{\cdot}001$)*. However, after curative resection there was no significant difference in the distribution of tumour stage. Patients with complete obstruction showed a higher incidence of recurrence* ($P<0{\cdot}01$) *after curative resection, consequent to an increased incidence of local recurrence* ($P<0{\cdot}02$)*. Five-year cancer-specific survival for the total series was decreased from 59·1 per cent in patients without obstruction to 31·8 per cent in those with complete obstruction* ($P<0{\cdot}001$)*. After curative resection there was also a significant reduction in survival* ($P<0{\cdot}001$)*. It is concluded that completely obstructing colonic cancers are more aggressive than other colonic cancers.*

Keywords: Colonic neoplasms, intestinal obstruction, neoplasm, carcinoma, recurrence, survival

The occurrence of large bowel obstruction secondary to colonic carcinoma has been reported in 7–29 per cent of colorectal cancer patients[1–6].

The survival rate of patients with obstructing colorectal cancers is significantly less than that of patients without obstruction[1–4,7–9]. In addition, there has been reported an increased risk of surgical mortality, a higher incidence of lymph node metastases, and a decreased curative resection rate[1–3]. Many factors have been suggested for the poor prognosis, including advanced age, poor general condition of the patient, advanced stage of the tumour, poorer differentiation, greater risk of vascular invasion, and delay in removal of the tumour which occurs when staged methods of resection are used[1–6,9–11].

The present paper has analysed clinicopathological and survival data in an attempt to explain the poorer prognosis

Patients and methods

Between 1950 and 1984, 1030 patients were operated on by one of the authors (E.S R H) for carcinoma of the colon. The series included patients with rectosigmoid cancers, but excluded rectal cancers. The colon has been divided into two segments, right and left, the junction being defined as the mid-transverse colon

Patients with perforation in addition to obstruction form a separate group of cases and are excluded from the present analysis, as are those with synchronous and metachronous cancers; this resulted in 908 patients being eligible for analysis.

Complete obstruction was diagnosed in patients presenting with absolute constipation, abdominal pain and distension, and dehydration, constituting an acute abdomen requiring urgent resuscitation and surgical intervention. This accounted for 148 (16·3 per cent) patients.

Partial obstruction was present in 280 (30·8 per cent) patients; it was considered to be present in patients with obstructive symptoms but still passing flatus per rectum who, in addition, had radiological features of incomplete obstruction, confirmed by colonic distension at laparotomy.

Four hundred and eighty (52 9 per cent) patients had no evidence of obstruction clinically, radiologically or at operation.

Clinical features, tumour pathology (including differentiation) and staging according to Dukes' classification[12] with, in addition, advanced disease according to Whittaker and Goligher[13], resectability, postoperative mortality, recurrence rates, and cancer-specific survival have been compared Advanced disease was subdivided into two categories, ‘D’$_1$ included tumours with local visceral invasion and ‘D’$_2$ included those tumours with distant dissemination.

All patients with colorectal cancer were prospectively registered and clinical, operative and pathological findings were recorded. The patients were followed by one of the authors (E.S R.H.) every 3 months for the first year, every 6 months for the subsequent 2 years, and then annually[14].

All the data were coded in a form suitable for computer analysis, using the Statistical Package for the Social Sciences[15]. χ^2 statistical analyses have been used throughout Cancer-specific survival curves have been plotted according to the conditional probability method of Kaplan and Meier[16]. Statistical differences between survival curves were evaluated by the generalized Wilcoxon test according to Gehan[17]. By this method, cases are classified as either fails (uncensored data) or non-fails (censored data). Fail signifies death due to colonic cancer. Non-fails were patients known to be alive or who had died from causes other than colonic cancer. Patients who died from complications occurring within 90 days of operation (63 postoperative deaths) were excluded from the cancer-specific survival analysis as were six patients lost to follow-up. The majority of the 839 patients eligible for analysis of cancer-specific survival have been followed up for periods of between 5 and 30 years

Results

There were no significant differences between the partial obstruction and non-obstruction groups in any of the findings, and therefore, to clarify the text, detailed results of the partial obstruction group are presented only in the *Tables* and *Figures*.

Incidence

Of patients without obstruction, 226 (47·1 per cent) were men and 254 (52·9 per cent) were women with a median age of 61·1 years (range 26–94 years). In those with complete obstruction 61 (41·2 per cent) were men and 87 (58·8 per cent) were women with a median age of 62·4 years (range 22–92 years).

Clinical features

The presenting symptom of abdominal pain in completely obstructing colonic tumours was present in 126 (85·1 per cent) patients compared with 284 (59·2 per cent) patients without obstruction ($P<0{\cdot}002$).

Abdominal distension was present in 103 (69·6 per cent) patients with complete obstruction compared with 32 (6·7 per cent) with no obstruction ($P<0{\cdot}0001$).

Symptom duration was less than 1 month in 45 (30·4 per cent)

0007–1323/89/090965–05$3 00 © 1989 Butterworth & Co (Publishers) Ltd

patients with complete obstruction compared with 109 (22·7 per cent) patients without obstruction.

Tumour distribution

Of the 908 patients in the total series, 288 were right-sided cancers and 620 were left-sided cancers. There were 37 (12·8 per cent) completely obstructing tumours of the right colon and 111 (17·9 per cent) of the left colon. The proportions of right-sided and left-sided tumours presenting with complete obstruction was not significantly different. The distribution is detailed in *Table 1*.

Management

The details of management are given in *Table 2*.

A potentially curative resection was defined as one where there was no evidence of macroscopic tumour remaining at the conclusion of the operation or of tumour at the lines of resection of the operative specimen, after histopathological examination.

The patients were treated by standard resections appropriate to the tumour site and the presence of obstruction. After the mid-1960s there was a preference for one rather than two or more stage procedures, and increased numbers of extended right hemicolectomies and subtotal colectomies were performed for distal obstruction. Twenty-four patients with stage 'D'$_1$ tumours underwent potentially curative resection.

Curative resections were performed on 75 (50·7 per cent) patients with complete obstruction. This incidence was lower than in patients without obstruction, 339 (70·6 per cent) patients ($P<0·001$).

Of the 75 patients with complete obstruction treated by curative resection 48 (64 per cent) patients had a primary resection and 27 (36 per cent) had a staged procedure. Only three patients without obstruction underwent a staged procedure.

Operative mortality

There were 13 postoperative deaths in patients with complete obstruction, a mortality rate of 8·8 per cent which was not significantly different from that in patients without obstruction (6·3 per cent: 30 deaths). After curative resection the postoperative mortality rate did not differ significantly between groups, being 6·7 per cent (five patients) and 4·4 per cent (15 patients), respectively.

The postoperative mortality rate in those with complete obstruction undergoing primary resection was 7 per cent (five of 70), which did not differ significantly from those undergoing staged procedures, 5 per cent (three of 57). After curative resection for one compared with two or three stage procedures for patients with complete obstruction, the postoperative mortality was 6 per cent (three of 48) and 7 per cent (two of 27), respectively, which did not differ significantly from that in patients without obstruction, 4·5 per cent (15 of 337) and zero (out of two), respectively.

The postoperative mortality rate after curative resection for right colonic tumours with complete or no obstruction was 3·7 per cent and 3·8 per cent, respectively. The corresponding mortality rates for left-sided tumours were 14·3 and 5·9 per cent. The differences were not significant.

The postoperative mortality rates after palliative resections in patients with complete obstruction and no obstruction were 6 and 14·5 per cent, respectively. The mortality rate after palliative bypass procedures in patients without obstruction was 7 per cent; no such procedures were performed in those with complete obstruction. Only one patient with complete obstruction underwent a diagnostic laparotomy alone and survived operation; the postoperative mortality rate was 5·9 per cent in the non-obstruction group.

The postoperative mortality for the periods 1950–65 and 1966–84 did not differ significantly between groups, both for the total series and after curative resection.

Pathology

Tumour staging. Tumour staging for the total series is detailed in *Table 3*. In the complete obstruction group there were only 11 (7·4 per cent) patients with Dukes' A tumours compared with 86 (17·9 per cent) patients in the group without obstruction ($P<0·005$). There was no significant difference in distribution of Dukes' B and C tumours. In the group without obstruction only 119 (24·8 per cent) patients had Dukes' 'D' tumours, which was significantly less than in the complete obstruction group where 58 (39·2 per cent) patients had Dukes' 'D' ($P<0·0005$).

Among those undergoing curative resection there were no significant differences in tumour stage distribution between patients with no obstruction or complete obstruction.

Tumour differentiation. Details of tumour differentiation were known in 316 patients without obstruction and 69 patients with complete obstruction. Tumour differentiation was divided into two groups, well differentiated tumours and other tumours

Table 1 *Tumour site distribution in 908 patients with colonic carcinoma*

	Right colon ($n=288$)	Left colon ($n=620$)
No obstruction	158 (54·9)	322 (51·9)
Partial obstruction	93 (32·3)	187 (30·2)
Complete obstruction	37 (12·8)	111 (17·9)

Table 4 *Local and distant recurrence after curative resection*

	Total	No recurrence	Local only	Distant only	Local and distant
No obstruction	339	253 (74·6)	25 (7·4)	37 (10·9)	24 (7·1)
Partial obstruction	185	140 (75·7)	13 (7·0)	22 (11·9)	10 (5·4)
Complete obstruction	75	44 (58·7)	10 (13·3)	11 (14·7)	10 (13·3)

Values in parentheses are percentages

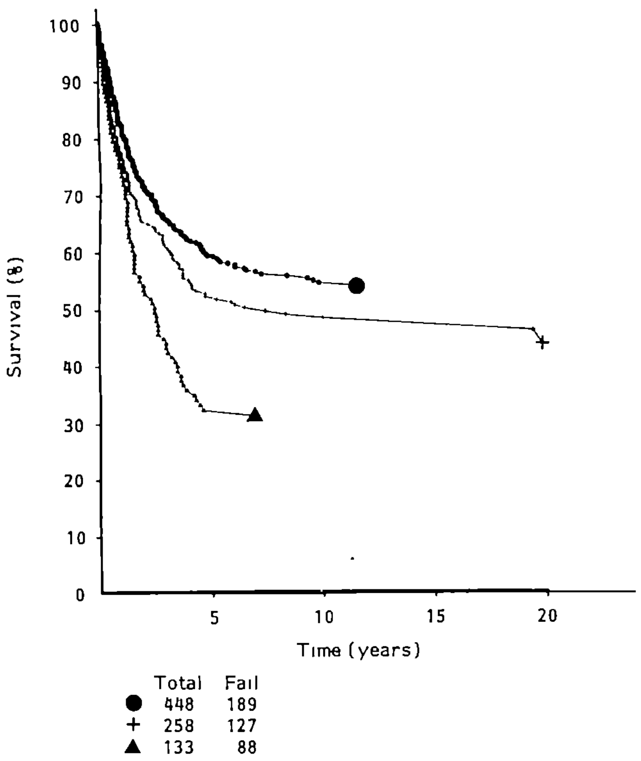

Figure 1 *Cancer-specific survival rates in relation to no obstruction* (●), *partial obstruction* (+) *or complete obstruction* (▲) *for the total series. Patients dying from complications within 90 days are excluded from the analysis Fail signifies death due to cancer of the colon; each mark on the survival curve represents an individual patient's death due to recurrent cancer of the colon. The heavier markings during the earlier postoperative years are consequent to an increased frequency of deaths during this period. Each survival curve attains a plateau after the last mark which represents the time of death of the patient who to date has survived the longest before dying from cancer of the colon The no obstruction and complete obstruction groups have been followed up for a comparable period to that of patients with partial obstruction. Survival is significantly worse comparing partial with no obstruction* ($P<0·04$) *and comparing complete with no obstruction* ($P<0·001$)

which included undifferentiated, poorly and moderately differentiated tumours. Forty-eight (15·2 per cent) tumours were well differentiated in those without obstruction. This incidence did not differ significantly from the 7·2 per cent (five patients) in those with complete obstruction.

Vascular invasion. There were no significant differences in the frequency of vascular invasion between patients with complete obstruction and no obstruction after curative or palliative resection.

Recurrence

Thirty-one (41·3 per cent) patients with complete obstruction developed recurrence (local and/or distant) after curative resection compared with 86 (25·4 per cent) patients in the non-obstructed group ($P<0·01$).

Details of local, distant, and local with distant recurrences are given in *Table 4*. Local recurrence was more frequent after complete obstruction compared with no obstruction ($P<0·02$), but distant recurrence did not differ significantly between groups.

Survival

Cancer-specific survival of patients with complete obstruction was significantly lower than for those without obstruction, both in terms of the total treated operatively and those managed by curative resection (*Figures 1* and *2*).

Cancer-specific survival rates after 5 years for patients with complete obstruction was significantly less than for patients without obstruction, being 31·8 and 59·1 per cent, respectively ($P<0·001$). After curative resection, 5-year cancer-specific survival rates were 54·1 and 78·9 per cent, respectively ($P<0·001$).

Cancer-specific survival after 5 years in patients with Dukes' A, B and C tumours who had curative resection are detailed in *Table 5*. For Dukes' B and C tumours there was a worse survival in patients with complete obstruction compared with no obstruction ($P<0·02$ and $P<0·05$, respectively).

Figure 3 compares cancer-specific survival in patients with complete obstruction undergoing primary and staged curative resections. Whilst the survival rate would appear to be improved for a primary resection (58·6 per cent 5-year cancer-specific survival) *versus* a staged resection (45·8 per cent 5-year cancer-specific survival), the difference did not reach significance ($P<0·13$). The same group of patients was further subdivided into right-sided and left-sided tumours (*Table 6*) Again, primary resection appears to show an increased survival compared with staged resections for both right and left colons but the difference was not significant. Nor was there a significant survival difference between right-sided and left-sided tumours.

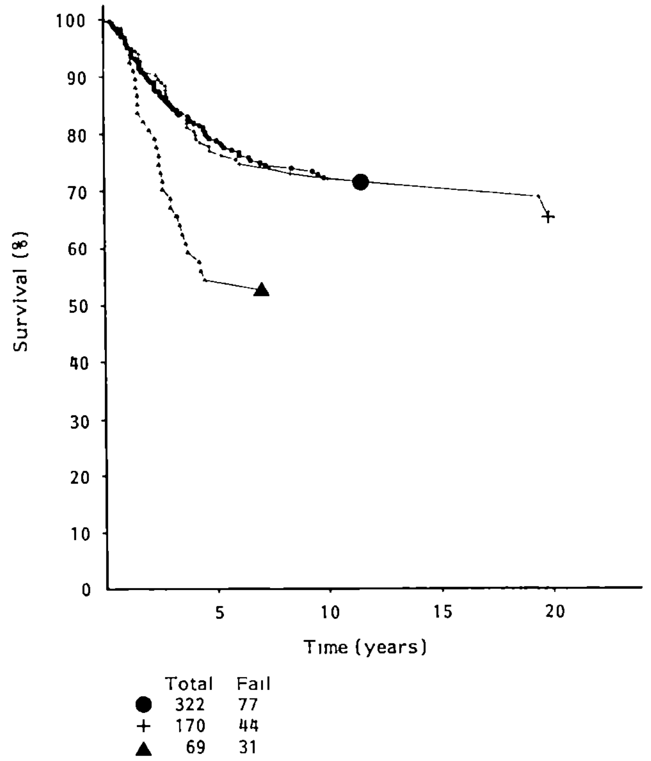

Figure 2 *The cancer-specific survival rate after curative resection is significantly poorer when complete obstruction* (▲) *is compared with no obstruction* (●) *or partial obstruction* (+) ($P<0·001$) *Each mark on the survival curves represents an individual patient's death due to recurrent cancer of the colon, fail signifies death due to cancer of the colon*

Table 5 *Five-year cancer-specific survival rates after curative resection for 520 patients with Dukes' A, B and C tumours*

	Dukes' A		Dukes' B		Dukes' C	
	No. of patients	5-year survival (%)	No. of patients	5-year survival (%)	No. of patients	5-year survival (%)
No obstruction	78	91·7	143	77·5	79	68·7
Partial obstruction	36	85·4	84	85·9	39	59·4
Complete obstruction	10	77·8	38	61·3	13	27·7

Table 6 *Five-year cancer-specific survival rates after primary and staged curative resection for complete obstruction*

	Right colon		Left colon		Total	
	No. of patients	5-year survival (%)	No. of patients	5-year survival (%)	No. of patients	5-year survival (%)
Primary resection	15	51·4	30	63·1	45	58·6
Staged resection	3	33·3	21	47·6	24	45·8

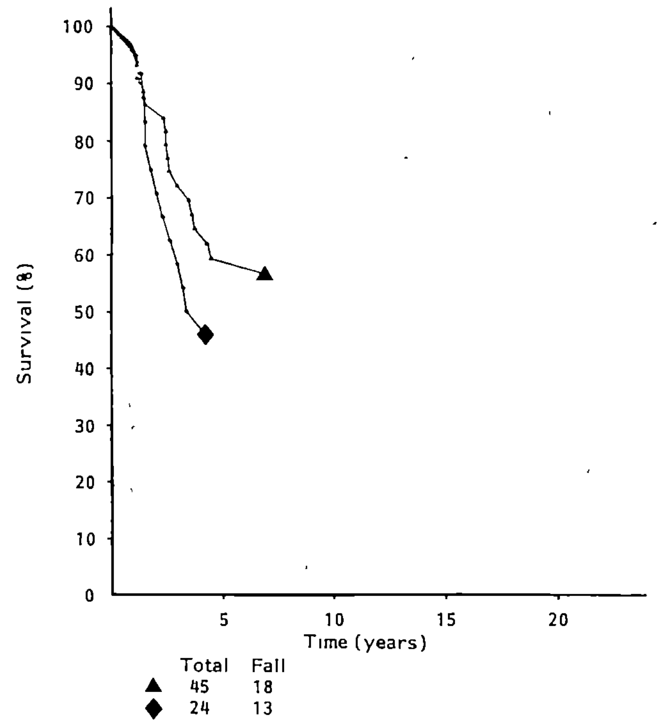

Figure 3 *The cancer-specific survival rate did not differ significantly between patients undergoing a primary (▲) or a staged (◆) curative resection for complete obstruction* (P<0·13). *Each mark on the survival curve represents an individual patient's death; fail signifies death due to cancer of the colon*

Comparison was made of cancer-specific survival for patients managed between 1950–65 and 1966–84. The 5-year survival rates were not significantly different comparing those having complete obstruction with those having no obstruction, both for the total series and after curative resection.

Discussion

The incidence of complete bowel obstruction due to colonic cancer (16·3 per cent) in this series closely resembles that reported by others[1–3,5,6,8]. The incidence of partial bowel obstruction (30·8 per cent) is considerably higher than that reported (10·2 per cent) by Ragland *et al.*[10]; however, the characteristics of those with partial obstruction have not previously been documented. The shorter symptom duration in patients with complete obstruction may point to a more rapid growth in obstructing cancers compared with non-obstructing cancers[18,19] Although there were greater numbers of left-sided obstructing tumours, as reported by others[5,20], the incidence of obstruction in the left colon compared with the right colon was not significantly different.

For the total series, in those with complete obstruction there were significantly fewer Dukes' A lesions and a greater number of Dukes' 'D' cancers compared with those without obstruction, which is in accordance with Umpleby and Williamson[3] and Dutton *et al.*[8], confirming that obstructing tumours were more locally advanced, with distant metastases being more common. This is reflected in the lower curative resection rate and poorer cancer-specific survival. The lower curative resection rate for completely obstructing tumours (50·7 per cent) compared with those without obstruction (70·6 per cent) is in agreement with several other series[1,3,21] but at variance with Dutton *et al.*[8] who reported a curative resection rate of 66·8 per cent in obstructed cases and a rate of 68·2 per cent for elective cases.

The postoperative mortality rate is based on the number of deaths due to complications occurring within 90 days of operation, and includes that of patients managed by staged resection. The mortality rates given are consequently approximately 1–2 per cent greater than those based on deaths occurring within 1 month of operation. The postoperative mortality rate after curative resection did not differ significantly between groups and attained 6·7 per cent for patients with complete obstruction. Other reports have given a considerably higher postoperative mortality rate in patients with complete obstruction of between 15 and 38 per cent[2,3,8,22–26], although in a related series of left-sided large bowel emergencies a rate of 8·5 per cent has been reported[27]. Furthermore, contrary to Waldron *et al.*[23,28], the mean age of patients in the groups varied from 60 to 63 years, those undergoing emergency surgery for obstruction being of a similar age to those undergoing elective procedures. This is reflected in a similar postoperative mortality rate for elective and emergency procedures.

In addition, contrary to these reports, the postoperative mortality rate did not differ significantly between primary and staged procedures, and is in accordance with Ohman[1]. Further, no significant difference in postoperative mortality rate was found comparing right-sided tumours with left, nor was there a difference in the periods 1950–65 and 1966–84. Hence we refute the suggestion by Waldron *et al.*[23] and Irvin and Greaney[2] that the worse prognosis is due to an increased perioperative mortality.

Several authors[1,5,22] have shown that the postoperative mortality rate for patients with complete obstruction has differed markedly between different surgeons, and that mortality has been less in patients operated on by consultant surgeons than by surgeons in training.

In the present series of patients with complete bowel obstruction, survival prospects did not differ between 1950–65 and 1966–84, both for the total series and after curative resection.

The poorer survival for patients with complete obstruction was not consequent to a higher postoperative mortality but to a decreased cancer-specific survival.

The cancer-specific survival was significantly reduced in patients with complete obstruction, for the total group, for those managed by curative resection, and for those with Dukes' B or C tumours.

The overall reduction in survival was related to an increased frequency of disseminated cancers, and this is in agreement with Willett *et al.*[29]. However, after curative resection the poorer cancer-specific survival was not related to any significant difference in tumour stage distribution, tumour differentiation, or degree of vascular invasion. In those with complete obstruction there was a significant increase in local recurrence and, although for those undergoing curative resection the stage distribution of tumours was similar, within Dukes' B and C tumours there was a significantly worse survival rate for those with complete obstruction. These findings suggest that colonic cancer presenting with complete obstruction is more aggressive than other colon cancers. It is not known whether the obstruction process itself influences the relationship between the tumour and host resistance. We conclude that there is another as yet unmeasured factor operating in those with obstruction resulting in the poorer prognosis.

In the present series, survival appeared to be improved for a primary *versus* a staged curative resection in patients with completely obstructing cancers, although the difference did not reach statistical significance. This finding is in accordance with Fielding and Wells[30], and others[2,3,31]. However, Ohman[1] and Phillips *et al.*[5] have reported opposing results, and further studies are required

Mr D. Z. Lubowski

In an attempt to improve continence after restorative proctocolectomy, ileal reservoir–anal anastomosis at the level of the anorectal junction has been advocated. This procedure preserves the entire mucosa of the anal canal. The histological appearances of the anal mucosa have been examined in 16 consecutive patients undergoing restorative proctocolectomy for ulcerative colitis. In 14 patients there was chronic inflammation characteristic of ulcerative colitis. Four patients had moderate dysplasia and in one of these patients an unsuspected adenocarcinoma of the anal canal extending down to the level of the dentate line was present. We believe that the anal mucosa should always be removed down to the level of the dentate line in restorative proctocolectomy for ulcerative colitis.

Keywords: Anus, restorative proctocolectomy, ulcerative colitis

Restorative proctocolectomy with ileal reservoir is now an established form of surgical treatment for ulcerative colitis and familial adenomatous polyposis The procedure satisfies the principles of excisional surgery for these conditions as it removes all diseased mucosa[1,2]. There has been considerable debate about which design of ileal reservoir produces the best functional results[3–5]. However, most have agreed on the importance of removing the entire anorectal mucosa as far as the level of the dentate line[3,4,6] because the anal canal may be lined with columnar mucosa down to this level[7], with consequent risk of neoplastic change

In an attempt to improve continence after restorative proctocolectomy Johnston *et al.* have carried out stapled reservoir–anal anastomosis at the level of the pelvic floor, thereby leaving intact the mucosa of the upper part of the anal canal[8]. We have examined the anal mucosa in a group of patients undergoing restorative proctocolectomy for ulcerative colitis to see how frequently the inflammatory process involved this area and to assess the potential danger of not excising the anal mucosa in this procedure.

Patients and methods

Sixteen consecutive patients undergoing restorative proctocolectomy for ulcerative colitis were studied A two-loop (J) reservoir was made in eight patients, a three-loop (S) reservoir in one, and the remaining seven patients had a four-loop (W) reservoir as previously described[4] The rectum was mobilized and divided at the level of the pelvic floor and the anal mucosa was removed peranally from the level of the dentate line up to the divided end of the anorectum. In some cases after mobilizing the rectum the muscle of the lower rectum was incised circumferentially and dissection was carried out in the submucosal plane down to the level of the anorectal junction The dissection was then completed by peranal excision of the anal mucosa from the level of the dentate line cranially to meet the abdominal dissection In each case the entire anal mucosa was removed down to the level of the dentate line.

Sections from the anal mucosa were taken from the dentate line to about the level of the anorectal junction and stained with haematoxylin and eosin The mucosa was examined with light microscopy for features of ulcerative colitis. Dysplastic changes were graded as mild, moderate or severe according to accepted criteria[9] Dysplasia was said to be present only when the cellular changes were considered to be beyond those that might accompany mucosal inflammation

Results

The anal mucosa was columnar proximally and squamous in the transitional zone in 13 patients, and in three patients the mucosa was columnar-lined down to the dentate line. Sections from 14 of the 16 patients showed chronic inflammatory changes characteristic of ulcerative colitis (*Figure 1a*) and in ten patients there was active inflammation. Moderate dysplasia was observed in four patients (*Figure 1b*). In one of these four patients there was invasive poorly differentiated adenocarcinoma of the anal canal, which extended down to the edge of the divided anal mucosa at the level of the dentate line (*Figure 2*). The rectum showed the severe inflammatory changes of chronic ulcerative colitis with mild dysplasia but the carcinoma was confined to the anal canal. Abdominoperineal excision of the pouch and anus with permanent ileostomy was carried out 2 weeks after the initial procedure.

Discussion

The presence of inflammation and dysplasia in the anal mucosa in a significant proportion of patients with ulcerative colitis in this study suggests that there may be a considerable risk in not removing the anal mucosa in restorative proctocolectomy. The rationale for leaving intact the mucosa of the upper anal canal in restorative proctocolectomy has been to improve the functional results of this procedure[8]. Some studies have reported a high incidence of minor degrees of incontinence after restorative proctocolectomy with ileoanal anastomosis at the dentate line[3,5,10] and Johnston *et al.* have suggested that continence is improved with stapled reservoir–anal anastomosis at the level of the anorectal junction compared with endoanal sutured anastomosis 1 cm above the dentate line[8].

Two possible mechanisms whereby this stapling technique might improve continence have been postulated[8]. First, the technique eliminates retraction of the anus during stripping of the anal mucosa and during ileoanal anastomosis. There is evidence that patients with minor incontinence after restorative proctocolectomy have lower resting anal pressures than patients with normal continence[8,11], indicating that internal anal sphincter damage may be the cause of the impaired continence. Nevertheless, some studies have found normal continence in over 90 per cent of patients after restorative proctocolectomy with excision of the anal mucosa[3,4] and, even allowing for differences

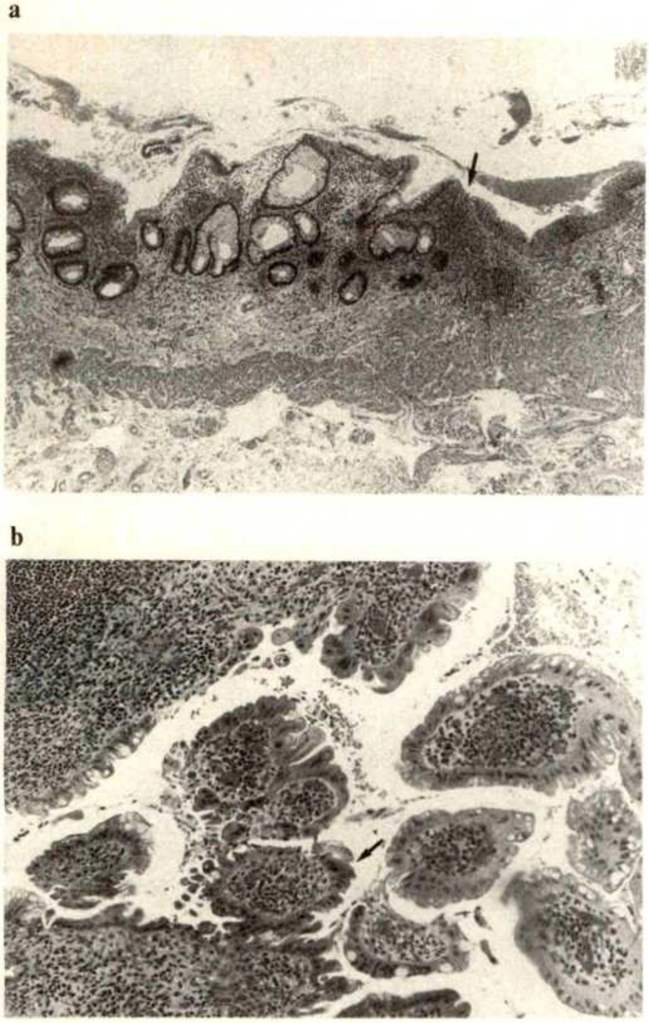

Figure 1 **a** *Anal canal mucosa showing the squamocolumnar junction (arrow). There is inflammation with ulceration, and crypt deformity and dropout*. **b** *Anal mucosa showing chronic inflammation, with mucosal dysplasia (arrow)*

in criteria for defining minor incontinence, it seems likely that normal continence can be achieved in the majority of patients by reducing the length of time of anal retraction.

Second, the stapling technique preserves the anal mucosa[8]. It has been suggested that the anal transitional zone, which extends from the dentate line to the columnar ('rectal') epithelium[7], as well as the columnar epithelium in the upper anal canal itself, may be important in maintaining continence after restorative proctocolectomy[8,12]. However the role of the anal mucosa in the normal continence mechanism remains uncertain[13]. 'Sampling' of the rectal contents by the anal mucosa is thought by some to be important[14] and apparent sampling responses have recently been found in ambulatory recordings of anorectal pressures[15]. However, anaesthetizing the anal mucosa does not impair continence in normal subjects[16]. Bartolo *et al.*[17] and Keighley *et al.*[18] showed objective evidence of reduced anal sensation after restorative proctocolectomy with excision of the anal mucosa including the transitional zone, as did Holdsworth and Johnston with excision of the mucosa to 1 cm above the dentate line[12]. However Keighley *et al.*[18] found in a small number of patients that this was not accompanied by impairment of continence or loss of the ability to discriminate flatus from stool. Furthermore, the high incidence of normal continence in some studies after excision of the anal mucosa[3,4,19] suggests that the anal mucosa was not essential for the preservation of continence in the majority of those patients.

The long-term risk of developing carcinoma in the rectum after ileorectal anastomosis for ulcerative colitis is only about 5 per cent with careful follow-up[20–22]. We have had no other case of anal adenocarcinoma occurring with ulcerative colitis. However, the small risk of developing anorectal carcinoma appears to be eliminated after total excision of the colonic and anorectal mucosa, which we believe should remain the fundamental aim of this procedure. Excluded islets of mucosal cells may be left behind after restorative proctocolectomy[23], but these cells have been shown not to be clinically relevant[24]. Early detection of anal carcinoma occurring adjacent to an ileoanal anastomosis might be difficult in some cases as induration or a slight irregularity might be attributed to the local effects of surgery.

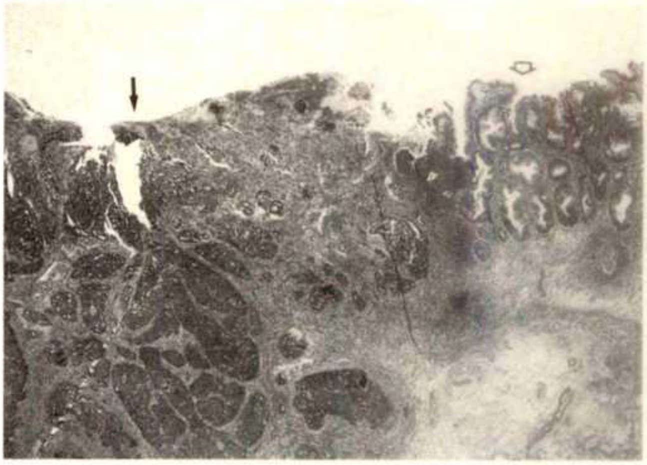

Figure 2 *Anal mucosa with columnar lining (proximal: open arrow), and invasive adenocarcinoma extending deeply into the submucosa (arrow). The anal canal was columnar-lined down to the distal surgical margin of the mucosa at the level of the dentate line*

It is possible that the histological changes observed in the mucosa in this study may have been modified by stripping of the mucosa. We have no preoperative anal biopsies to compare with the excised mucosa. Nevertheless, the major histological features were of chronic inflammatory changes with ulceration (*Figure 1*).

We were concerned that the anal carcinoma reported in this study was not recognized preoperatively. Examination of the histological sections shows a flat lesion with adjacent benign ulceration (*Figure 2*). Malignant change within this inflamed, ulcerated area was not even recognized by close inspection during endoanal mucosal excision.

Although the most distal part of the anal mucosa is usually not columnar epithelium, in a small proportion of patients in this study columnar epithelium was found down to the dentate line, as has previously been well described[7]. As it is not known whether this mucosa is squamous or columnar without histological examination, it is necessary to excise the entire transitional zone in all patients in order to remove the columnar epithelium in every case. Deasy *et al.*[25] found that the anal transitional zone was 'mildly inflamed' in 39 per cent of 31 patients undergoing total proctocolectomy for ulcerative colitis. However, 87 per cent of our patients had inflammation in the anal mucosa and in four of 16 dysplasia was present. For this reason, and because the transitional zone does not appear to be essential for normal continence, we would advocate complete excision of the anal mucosa in restorative proctocolectomy, with ileoanal anastomosis at the level of the dentate line.

Contents: Introduction: The Role of Surgery in Cancer Treatment. – Biology of Cancer. – Detection and Diagnosis. – General Concepts in Cancer Treatment. – Emergencies in Cancer Disease. – Rehabilitation Procedures. – Planning and Evaluation of Cancer Treatment. – Treatment and Cancer of Different Organs. – Subject Index.

In oncology today the accent lies on a multidisciplinary approach, and consequently this handbook aims to provide wide-ranging information regarding all aspects of the surgical treatment of cancer. It deals with the basic subjects: the biology of cancer, detection and diagnosis, and treatment concepts. From screening to the application of markers, from new transplantation techniques to psychological aspects, an overall picture is presented. The surgeon will find chapters to enhance his knowledge of those areas which may not have required his attention until now. This volume should serve as a valuable reference for many years to come.

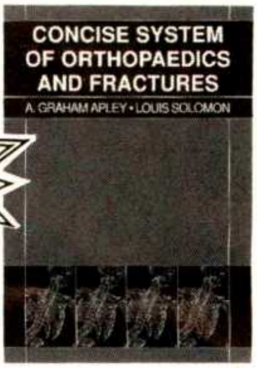
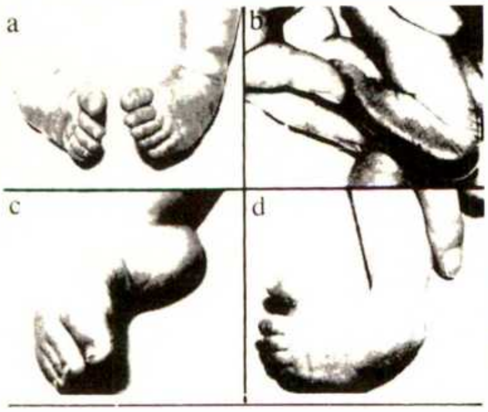
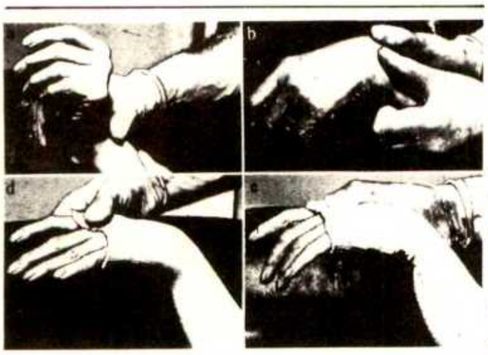
AVAILABLE ON INSPECTION



CONCISE SYSTEM OF ORTHOPAEDICS AND FRACTURES
A. GRAHAM APLEY • LOUIS SOLOMON

★ A shorter, revised version of the classic 'Apley's System' ★ Same systematic presentation – ideal for learning and revising ★ Nearly 500 illustrations, many presented as composites ★ Meets the needs of undergraduate and paramedical students





Apley's System of Orthopaedics and Fractures has for long been an established favourite. But it is a textbook designed primarily for postgraduates, and for many readers it is unnecessarily detailed. This new *Concise System* is a distillation of the larger book and will meet the needs of those looking for an introductory account of modern orthopaedics.

Systematic, balanced and easy to use, the *Concise System* is an outstanding textbook of orthopaedics for anyone seeking a brief account of this large subject. It is also a natural precursor to the more detailed coverage of the subject offered by its larger parent.

Contents

Part 1 General Orthopaedics
Diagnosis in orthopaedics · Infection · Rheumatic disorders · Gout and degenerative arthritis · Bone necrosis · Metabolic and endocrine disorders · Bone dysplasias · Tumours · Neuromuscular disorders · Peripheral nerve lesions · Orthopaedic operations

Part 2 Regional Orthopaedics
The shoulder · The elbow · The wrist · The hand · The neck · The back · The hip · The knee · The ankle and foot

Part 3 Fractures and Joint Injuries
Fracture pathology and diagnosis · Principles of fracture treatment · Complications of fractures · Stress fractures and pathological fractures · Injuries to joints · Injuries of the upper limb · Injuries of the spine, thorax and pelvis · Injuries of the lower limb

Index

October 1988 336 pages 234 x 165 mm Softcover Illustrated – 375 halftones and 95 line drawings 0 407 00325 8 £14.95

Comparison of digital and manometric assessment of anal sphincter function

Anal sphincter function was assessed by digital examination and anal canal manometry in 66 patients and controls. Digital scores were allotted by using visual analogue scales for basal and squeeze sphincter function and were compared with the corresponding pressures. There were good correlations between digital basal score and maximum basal pressure (Spearman rank correlation coefficient $r_S = 0\cdot56$, $P < 0\cdot001$)*, and digital squeeze score and maximum squeeze pressure* ($r_S = 0\cdot72$, $P < 0\cdot001$)*. There were wide ranges of sphincter function on digital and manometric assessment with considerable overlap between patient groups. Digital scores detected differences in sphincter function between patient groups as accurately as manometry. The sensitivities and specificities of digital scores and anal canal manometry in segregating continent and incontinent patients were similar. It was concluded that digital estimation was equally as good an assessment of anal sphincter function as anal canal manometry.*

The primary function of the anal sphincters is to retain faecal matter within the rectum until a propitious time arrives for its controlled expulsion. Sphincter strength has been assessed by manometry using a variety of techniques[1]. The internal anal sphincter contributes 85 per cent of resting anal tone, and the external anal sphincter provides the squeeze increment[2]. Resting and squeeze anal canal pressures are reduced in faecal incontinence[3,4]. Other more sophisticated investigations such as fibre density measurement, pudenal nerve terminal motor latency[5] and motor unit potential duration[6] have demonstrated denervation of the external anal sphincter and puborectalis in idiopathic faecal incontinence.

Anal canal manometry, when available, often influences clinical decisions in anorectal surgery. Patients with low anal canal pressures will be offered abdominoperineal excision of the rectum for cancer, rather than a low anterior resection. Similarly, patients with low pressures are more likely to be incontinent after an ileoanal pouch procedure and might therefore be offered an end ileostomy.

However, the majority of general surgeons do not have access to anal canal manometry and their decision about which surgical procedure is appropriate in a case where continence is potentially threatened is based on assessment of anal sphincter function solely by digital examination.

The aim of this study was to compare digital estimation of anal sphincter function with a standard manometric measurement of sphincter tone, and to compare the ability of the two assessments of sphincter function to discriminate between the sphincter strength in groups of patients with faecal incontinence, severe constipation and normal control.

Patients and methods

Twenty-two asymptomatic subjects (20 women, two men, median age 43 years, range 38–47 years) undergoing minor surgical procedures unconnected with the anorectum, 22 severely constipated patients (20 women, two men, median age 35 years, range 19–47 years) and 22 faecally incontinent patients (21 women, one man; median age 66 years, range 50–85 years) were included in the study. The groups were matched for sex but the incontinent patients were significantly older than the other groups ($P < 0\cdot01$, Mann–Whitney *U* test)

With the patients lying in the left lateral position a digital rectal examination was performed and careful note was made of anal tone at rest and on a maximal voluntary contraction of the anal sphincter Marks were made on two separate non-continuous visual analogue scales (*Figure 1*), one for basal sphincter tone and one for squeeze tone The scales extended from zero at one end, representing no tone, to ten at the other end, representing the maximum tone conceivable Basal and squeeze scores were then allotted according to the position of the marks on the two scales. Analogue scales are the best available method of assessing subjective data, e.g degree of pain[7,8], and were felt to be the most appropriate method for digital assessment of anal sphincter function Once the marks for basal and squeeze scores had been placed on the scales the anal canal pressures were measured manometrically A water-filled system was used which consisted of a microballoon 4 mm in diameter connected to a Bell and Howell pressure transducer (Type 4-422-0001, Bell and Howell Ltd , UK), Lectromed amplifier (MX4P-145) and Lectromed chart recorder (Multi Trace 4; Lectromed Ltd , Jersey, UK) After calibration and determination of zero against the anal verge, the microballoon was inserted into the rectum. The pressures were recorded at rest and on a maximal voluntary squeeze contraction of the sphincter at 1-cm stations from 5 to 0 cm from the anal verge. The maximum basal pressure and maximum squeeze pressure were recorded[9]

The normal range, defined as including 95 per cent of the values obtained in the normal subjects, was determined for maximum basal

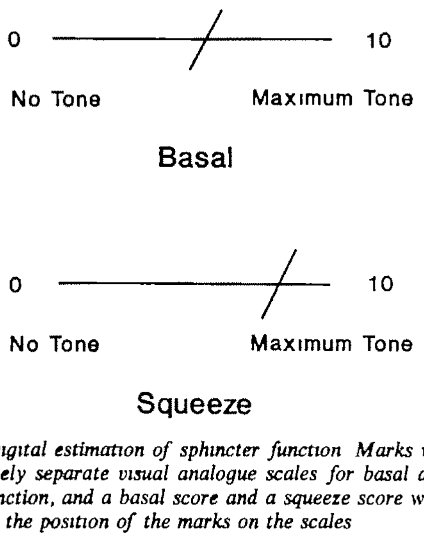

Figure 1 *Digital estimation of sphincter function Marks were placed on two entirely separate visual analogue scales for basal and squeeze sphincter function, and a basal score and a squeeze score were allotted according to the position of the marks on the scales*

pressure, maximum squeeze pressure, basal score and squeeze score. The lower limit of normal sphincter function was used to calculate the specificities and sensitivities of basal and squeeze manometric and digital sphincter functions, in discriminating between the continent and incontinent patients.

In a separate study the interobserver variability of digital and manometric assessment of anal sphincter function was compared in 14 patients. One investigator and one of three other surgeons experienced in anorectal physiology performed both digital and manometric assessment of sphincter function as described above.

All of the investigations were performed by the same surgeon (R.I.H.), with the exception of one arm of the interobserver variation study.

Spearman ranked correlation was used to compare manometric pressures and digital scores, and also for analysis of interobserver variation. The Mann–Whitney *U* test was used to compare patient groups after the Kruskal–Wallis test had demonstrated a difference.

Results

There was a significant correlation between maximum basal pressure and basal score ($r_S=0{\cdot}56$, $P<0{\cdot}001$; *Figure 2*) and a significant correlation between maximum squeeze pressure and squeeze score ($r_S=0{\cdot}72$, $P<0{\cdot}001$; *Figure 3*) when data from all patient groups were considered together.

There was a large overlap of basal anal sphincter function between all three patient groups for both maximum basal pressure and digital basal score (*Figure 4*). There was no significant difference between the control and constipated groups on manometry and digital score. The incontinent patients had a significantly lower basal sphincter function than the controls on both manometry ($P=0{\cdot}001$) and digital assessment ($P<0{\cdot}001$). The incontinent patients also had a significantly poorer basal sphincter function than the constipated patients on manometry ($P=0{\cdot}005$) and digital assessment ($P=0{\cdot}005$).

The findings for squeeze sphincter function were similar (*Figure 5*). There was a large degree of overlap of both maximum squeeze pressure and squeeze scores in all the patient groups. The incontinent patients had a significantly poorer squeeze function than both the control subjects ($P<0{\cdot}001$) and constipated patients ($P<0{\cdot}001$) on both digital and manometric assessment. Digital assessment detected a difference in squeeze function between the constipated and control patients ($P=0{\cdot}01$) which was not significant on manometry.

The sensitivities and specificities of manometric and digital assessment of basal and squeeze anal sphincter function in distinguishing the incontinent patients from the continent patients are shown in (*Table 1*). The sensitivities and specificities of maximum basal pressure and basal score were similar. The specificity of maximum squeeze pressure and squeeze score was similar, but the squeeze score was 21 per cent more sensitive than maximum squeeze pressure.

In the interobserver variation study there was a good correlation for maximum basal pressure ($r_S=0{\cdot}77$, $P=0{\cdot}001$), but not for basal score ($r_S=0{\cdot}49$, $P=0{\cdot}07$). There was a good correlation for maximum squeeze pressure ($r_S=0{\cdot}66$, $P=0{\cdot}01$) and also for the squeeze score ($r_S=0{\cdot}72$, $P=0{\cdot}004$).

Discussion

We have shown a significant correlation between digital and manometric assessment of basal and squeeze anal sphincter function. Felt-Bersma *et al.*[10] have also compared digital and manometric assessment of anal sphincter function. These authors characterized basal and squeeze sphincter strength into four groups (weak, moderate, normal and high) and their correlation coefficients were almost identical to ours. They did not compare the ability of manometry and digital estimation to discriminate between the sphincter function of different patient groups Two publications have commented that digital estimation does not correlate with anal canal manometry, but neither gave details of methods of comparison or the data on which the conclusions were based[3,11]

There was a wide range of anal canal pressures and digital scores in each of the three patient groups, with considerable overlap similar for manometric and digital estimation. Despite the overlap, digital estimation was able to discriminate sphincter function between the patient groups as effectively as anal canal manometry.

The sensitivities and specificities of digital estimation of anal sphincter function in discriminating symptomatic patients with and without incontinence were acceptable and similar to manometry. The squeeze score, however, had a higher sensitivity of 77 per cent; maximum squeeze pressure had a lower sensitivity of 56 per cent.

The remarkable similarity in the ability of anal canal manometry and digital estimation to discriminate between continent and incontinent sphincters is a tribute to the dense sensory innervation of the index finger. In addition anal canal manometry assesses only limited aspects of internal and external anal sphincter function, which themselves form only a part of the anal continence mechanism. The degree of sphincter recruitment in response to stress as well as absolute strength is of importance in the maintenance of continence[12]. The puborectalis muscle[13], rectal sensation, stool consistency[14] and sampling of rectal contents by the anal transition zone[15] are other important factors. A role has also been suggested for the anal cushions[16]. Digital estimation may perhaps give a more global assessment of the continence mechanism than manometry, which can only measure, perhaps with greater accuracy, internal and external anal sphincter strength.

We are aware of the potential bias of the investigator knowing the patient's diagnosis before undertaking the digital and manometric assessment of anal sphincter function. Bias in allocating the digital scores would tend to lead to a greater segregation of the patient groups on digital assessment than on manometry. However, the overlap between the patient groups was very similar for digital scores and anal canal pressures, and we therefore do not believe that the results of this study can have been influenced significantly by this particular bias.

In conclusion we have demonstrated a good correlation between digital scores and anal canal pressures and have shown that digital assessment is as good as manometry in discriminating sphincter function between continent and incontinent patients. We believe that manometry retains a definite place in clinical assessment and research, especially in prospective studies where the same individual is unlikely to perform all investigations. Manometry when interpreted in conjunction with other anorectal physiological investigations, e.g. electromyography and integrated pressure–electromyographic proctography[17], provides valuable information.

Optimal assessment of anorectal function in complex cases should include these investigations. However, as a single investigation for clinical purposes, there is little to choose between digital and manometric assessment of anal sphincter function.

The aim of this study was to investigate the effect of dietary restrictions on the positivity rate and yield of neoplasia during a study based on Haemoccult® screening for colorectal neoplasia. Of 18 925 participants who completed Haemoccult tests on a normal diet, 647 (3·4 per cent) were positive. All repeated the test with dietary restrictions: 251 remained positive and underwent further investigations which revealed 35 carcinomas and 169 adenomas in 129 subjects. The remaining 396 were sent a further Haemoccult test at 3 months. Of these, 317 (80·1 per cent) completed the test: 31 (9·8 per cent) were positive. Further investigation of the 31 positive subjects revealed four carcinomas and 20 adenomas. Retesting with dietary restriction will reduce the false positive rate of Haemoccult when used for colonic cancer screening. However, if the retest is negative a further test should be performed. To minimize the adverse effect this may have on compliance, we have allowed an interval of 3 months to elapse before this retest is requested.

Keywords: Colorectal carcinoma, screening, faecal occult blood

Faecal occult blood tests are the most widely used screening tests for colorectal neoplasia and have been shown to detect asymptomatic carcinomas at a less advanced pathological stage than those occurring in a matched control population[1–3].

Although increased blood losses have been shown in association with colorectal carcinoma, there is wide variation and an overlap with blood loss occurring in normal individuals[4,5]. A compromise in the sensitivity of the test for blood has to be reached whereby the maximum number of carcinomas are detected without subjecting a large number of healthy individuals to a potentially hazardous investigation such as colonoscopy.

The Haemoccult® (Röhm Pharma, Darmstadt, FGR) test is the most widely used for screening purposes and is considered to have a sensitivity suitable for the above requirements. It comprises a guaiac gum impregnated paper; the haematin moiety of haemoglobin catalyses the oxidation of guaiac to yield a colour change on the application of hydrogen peroxide. However, foods containing naturally occurring peroxidase and ingested animal haemoglobin may also result in a positive reaction. To minimize the incidence of such false positive reactions, testing with strict dietary restrictions has been advocated, avoiding the foods listed in *Table 1*, both when rehydration of the test slide has been performed[6] and without rehydration[7], although Macrae *et al.*[6] recommended immediate investigation if rehydration was not used.

We feel that such an imposition is an inconvenience to the participants in a population screening study and have demonstrated a statistically significant decline of up to 30 per cent in compliance when this has been employed (W. M. Thomas and J. D. Hardcastle, unpublished results) For this reason, routine dietary restriction is not employed at the initial screen in the Nottingham colorectal cancer screening study. All patients with positive results are subsequently retested with dietary restrictions and only proceed to further investigation if they remain positive for faecal occult blood. However, because of the known pattern of intermittent bleeding from tumours[4], it is thought prudent to perform a further test in those who are negative following dietary restriction (i.e. those who have had one positive and one negative test). In order to avoid repeated testing in a short period of time, we elected to delay this test by 3 months, a period decided upon as being reasonable to the participants in the screening study.

Patients and methods

Following the successful completion of a pilot study[8], a controlled trial of faecal occult blood screening for colorectal carcinoma was started in Nottingham in 1984 This is now the largest randomized controlled trial worldwide[1].

Participants in the trial, aged 50–74 years, are identified from general practitioner registers After stratification by age and sex, they are randomized by household into a test group, who are sent faecal occult blood tests, and a control group who do not receive the tests. The development of colorectal neoplasia in both groups is monitored by scrutiny of the pathology records of the Nottingham hospitals, by the Trent Region Cancer Registry and by information supplied by general practitioners. Development of neoplasia in people leaving the area is monitored using the National Health Service Central Registry.

The test group were sent either 3-day or 6-day Haemoccult test packs, together with an explanatory letter from their family doctor inviting them to complete and return the test. These tests were performed without dietary restrictions. The completed Haemoccult slides were tested, without rehydration, and a blue discoloration at 30 s was considered a positive result. From May 1986, those individuals with a positive test were asked to repeat the test with standard dietary restrictions, including red meats and vegetables high in peroxidase (*Table 1*). If this test remained positive, the patient underwent a colonoscopy and, if necessary, a double-contrast barium enema. If the test was negative, the patient was not investigated but was asked to perform a further test with dietary restrictions after an interval of 3 months.

Cancers were staged according to Dukes' classification[9], to which was added a Dukes' 'D' for patients presenting with distant metastases or locally unresectable disease.

Results

During the test period, 18 925 people agreed to participate in the study (*Figure 1*). After the initial request to perform Haemoccult tests (i.e. without dietary restrictions), 647

Figure 1 *Outcome of screening by faecal occult blood test*

(3·4 per cent) were positive for faecal occult blood. They were asked to repeat the test with dietary restrictions (a compliance of 100 per cent was obtained): 251 people remained positive and were referred for further investigation. Thirty-five carcinomas (18 Dukes' A, nine Dukes' B and eight Dukes' C) and 169 adenomas in 129 patients were identified.

The 396 people who were negative for occult blood on dietary restriction testing were asked to participate in a further Haemoccult test at 3 months. Of these, 317 completed and returned the test, a compliance rate of 80·1 per cent; 286 (90·2 per cent) were found to be negative and 31 (9·8 per cent) positive. Investigation of the positive subjects revealed four carcinomas (one Dukes' A, one Dukes' B and two Dukes' C), and a total of 20 colonic polyps in 15 patients. These were all removed endoscopically; 17 were retrieved for histological examination, which demonstrated one villous adenoma, 11 tubulovillous adenomas and five tubular adenomas.

The median follow-up of these patients is 24 months, with a range of 18–33 months. To date, one patient in this group has presented with a symptomatic carcinoma 11 months after a negative test. He was found to have a carcinoma of the rectum with liver metastases.

None of the 79 patients who failed to complete and return the 3-month test has subsequently presented with large bowel neoplasia.

Discussion

Controversy persists regarding the ideal sensitivity of faecal occult blood tests used for screening purposes, and the role of dietary restrictions in those tests known to be affected by ingested animal haemoglobin or vegetable peroxidases.

The Haemoccult test is cheap, simple to perform and requires minimal laboratory expertise to interpret. In this study, 2·06 carcinomas and 7·61 patients with adenomas were detected per 1000 patients accepting the test[1]. The present rate of detection in the Nottingham trial is 2·30 carcinomas and 8·00 people with adenomas per 1000 accepting the test[1]. The randomized controlled trials have demonstrated that a significantly greater proportion of cancers detected by faecal occult blood tests are Dukes' A when compared with those occurring in the control populations[1–3]. Faecal occult blood tests are the most cost-effective method available for screening for colorectal neoplasia. The most expensive item in such a screening programme is the provision of endoscopic and radiological services to examine those individuals with positive tests. The adoption of a highly sensitive test for faecal occult blood, or a failure to allow for dietary factors, would result in the investigation by colonoscopy of many healthy individuals, producing a waste of available resources.

Retesting with dietary restriction has been advocated as a means of reducing the rate of dietary false-positive results and subsequent colonoscopy. Elliot *et al.*[10] used a further test after a 6-month interval in an attempt to minimize the number of false negative tests following a period of dietary restriction. No further cancers were detected in this series, although only half of those eligible had been retested at the time of the report.

In our study, 647 colonoscopic examinations would have been performed had retesting with dietary restriction not been employed. In fact 251 were performed following the initial retest, and a further 31 following the 3-month retest. Thus a saving of 365 (56·4 per cent) colonoscopies was achieved.

In addition to the financial savings, it is important to remember that unnecessary colonoscopy is an inconvenience to both patient and employer. Furthermore, there is a small but definite risk of a major complication, such as colonic perforation[11]. One carcinoma was probably missed at the time of the 3-month rescreen and this might have been detected if all those patients with positive tests at the initial screen had been investigated. However, had this been the policy, it would have been necessary to perform an additional 365 colonoscopies, greatly increasing workload and the risk of iatrogenic injury.

Although 100 per cent compliance was achieved for the initial request to repeat the test with dietary restrictions, it is of some concern that there was a deterioration in compliance at the 3-month rescreen, 79 (19·9 per cent) of those invited failing to complete this test. Of those who did complete the 3-month retest, four (1·3 per 100) were shown to have a carcinoma. This compares with an annual incidence of 0·1 per 100 persons in this age range, calculated from the age-specific incidence rates for England and Wales[12]. It would therefore appear that those who did not comply with the request to perform the 3-month rescreening test are at an increased risk of harbouring an asymptomatic carcinoma. However, with a median follow-up of 2 years, no such individuals have yet presented with symptomatic neoplasia.

As expected, the yield of neoplastic disease at the 3-month rescreening test is lower than that obtained in the select group in whom Haemoccult tests remained positive following a period of dietary restriction. Nevertheless, a further four carcinomas and 17 adenomatous polyps were detected, and the positive predictive value of the test for neoplasia is high (61·3 per cent) in this group.

There is no ideal faecal blood test for the detection of colonic neoplasia and a balance has to be achieved between the maximum detection of neoplasia and the minimum investigation of healthy individuals. At present we conclude that retesting with dietary restriction as described is justified, reducing the need for unnecessary investigations. However, there is a significant yield of neoplasia from the 3-month rescreening test and we advocate such testing for this group.

Case report

Br. J. Surg. 1989, Vol. 76, September, 978

Pneumoparotitis

M. R. Telfer and G. H. Irvine

Department of Oral and Maxillofacial Surgery,
Southmead Hospital, Bristol BS10 5NB, UK
Correspondence to: Mr G. H. Irvine

Pneumatic inflation of the parotid gland can be an occupational hazard in glass blowers and those who play wind instruments[1–6]. It has also been reported in children as an attention-seeking device[2,3].

Case report

A 29-year-old man complained of a 'squelching' noise and feeling in the right side of his face and ear. The problem had been present for 2 years, was worse in the morning and had remained constant except for exacerbations associated with upper respiratory tract infections. On inspection there was no facial abnormality. Palpation of the right side of the face elicited a 'squeaking' noise on movement of the tissues overlying the right parotid gland. This was not immediately recognizable as the characteristic feel of surgical emphysema but when the right parotid was milked, air bubbles were noticed coming from the duct whose orifice was grossly dilated. No underlying social or occupational factors were elicited.

Plain radiographs and an ultrasound scan of the area were normal but a right parotid sialogram showed dilated ducts containing air. During investigation it was noted that the buccinator on the right had little activity and the cheek was allowed to balloon out on blowing. It was considered that the normal sphincter mechanism of the buccinator muscle was inefficient.

The patient was anxious to receive treatment; the operation described by Wilkie and Brody[7] for the treatment of drooling was advised. The duct was lengthened and posteriorly repositioned by using a buried mucosal flap based on a periductal pedicle. The new orifice of the parotid gland came to lie at the anterior pillar of the fauces to which it was sutured. The anterior defect was closed primarily.

The patient made a satisfactory postoperative recovery, with the complete disappearance of his previous symptoms. He was discharged from follow-up after 4 months.

Discussion

Expiratory intraoral pressure is normally 2–3 mmHg. Maximal pressures of 140–150 mmHg may be recorded in glass blowers and trumpet players[3,4]. The incidence is highest in those who blow with full cheeks as opposed to those who blow with the cheeks contracted[3].

Passage of air into the parotid gland is prevented by the contracted buccinator muscle which compresses the duct, and distension of the cheek which increases the angulation of the duct at the point where it turns medially at the anterior border of masseter. Furthermore, the diameter of the duct orifice is smaller than the diameter of the duct itself, and the duct is usually slit-shaped with mucous membrane folds which seal when the intraoral pressure is raised[3].

The condition may be complicated by infection[1] or by the accumulation of secretions in dilated portions of the gland or duct. Rarely there may be extension of the emphysema into the subcutaneous tissues of the neck so requiring the possibility of a pneumothorax or rupture of a laryngocele to be considered[5].

The treatment of pneumoparotitis in adults has so far been unsatisfactory. However, the problem in children appears to be self-limiting and no treatment is required. Methods of promoting the flow of saliva and air from the gland have been suggested such as the use of local anaesthetic to block the periarterial sympathetic nervous system at the level of the superficial temporal artery so relaxing the sphincter of Stenson and contracting the ducts. This has been used in conjunction with infiltration of antibiotics directly into the duct[6]. Surgical treatment has included unsuccessful efforts to close off the orifice of the duct with small clamps, excision of the duct and the majority of the glandular tissue or simple ligation of the duct[5]. Finally, patients have been advised to change employment[6]. However, the method of surgical treatment suggested which is both well tried and certainly, in this case, successful would remove the need for this drastic piece of advice.

Acute primary hyperparathyroidism: experience of 59 cases

E. Sarfati, L. Desportes, D. Gossot and C. Dubost

Department of Visceral Surgery, Hôpital Saint Louis, 1 Avenue Claude Vellefaux, 75010 Paris, France

Correspondence to Dr E Sarfati

Acute primary hyperparathyroidism is a rare disease with a high mortality rate in some series. Between 1960 and 1986, 1000 patients were treated for primary hyperparathyroidism, among them 59 patients with acute hyperparathyroidism. All these patients were successfully operated on; none of them died before surgery. This study reveals the importance of resuscitation and urgent surgery. It is necessary to rehydrate, to correct electrolyte disorders and to lower serum calcium levels, but it is not necessary to obtain normal serum calcium levels before surgery.

Keywords: Acute primary hyperparathyroidism

Between 1960 and December 1986, 1000 patients were treated for primary hyperparathyroidism in our department. Fifty-nine of these patients (5·9 per cent) had acute hyperparathyroidism and underwent surgery. One patient died

Analysis of these records enabled us to put forward our diagnostic and therapeutic experience, and to emphasize the importance of resuscitation and urgent surgery. In most cases, patients underwent surgery within 48 h of admission to our department.

Patients and methods

This study was based on the analysis of 59 cases Criteria for the diagnosis of acute hyperparathyroidism were· surgically confirmed primary hyperparathyroidism with serum calcium levels $\geq$3·75 mmol/l (150 mg/l) and more than one severe clinical sign Forty per cent of the patients were considered critical at the time of admission. Ten patients with serum calcium levels $\geq$3·75 mmol/l, but without severe clinical signs, were excluded from the study.

Results

Forty-five women and 14 men with a mean age of 58 years (range 27–87 years) were included in this study. In 36 cases (61 per cent), primary hyperparathyroidism was discovered only after admission for an acute episode. Five patients (8 per cent) had known and documented hyperparathyroidism before admission. Twenty-one patients (36 per cent) had a typical but neglected past history of primary hyperparathyroidism. The incidence of clinical signs indicating the severity of hyperparathyroidism was very variable (*Table 1*). All patients had at least three severe signs, in various combinations, the most frequent signs being muscular weakness, an altered state of consciousness and dehydration. The time between the first appearance of symptoms of a high serum calcium and its clinical confirmation varied from a few days to several months. Since 1978, the measurement of serum calcium has become routine in hospitals, and the delay in diagnosis has become much less.

Serum calcium levels ranged from 3·75 to 5·62 mmol/l (150–224 mg/l; *Figure 1*). In 12 per cent of patients, serum calcium levels had been >4 mmol/l over a period of several months Serum phosphate levels ranged from 0 20 to 1·22 mmol/l; 53 per cent of patients had no evidence of low serum phosphate. Serum parathyroid hormone level was determined in 48 patients, but was known before surgery in only 32 cases. In all cases, the hormone levels were very high (4–30 times the normal).

Treatment before surgery

Before admission to our department, 56 patients received medical treatment in order to lower serum calcium levels. Six patients required only rehydration to re-establish normal electrolyte status. Fifty patients were treated with hypocalcaemic agents (frusemide, mithramycin, oral diphosphonates). The efficacy of the various treatments was difficult to assess as each one was administered at different dosages and in varying combinations. These drugs were always effective, and no complications occurred with frusemide and diphosphonates. By contrast, in 30 per cent of cases, reversible hepatic and haematological abnormalities were observed when mithramycin was included in the treatment. There was no evidence of combined drugs being more effective than single drug therapy When drug treatment was effective the benefit was transient. Two patients with serum calcium levels >5·50 mmol/l (220 mg/l) underwent haemodialysis, which resulted in an effective decrease of calcium levels to 3·00 mmol/l (120 mg/l) However in both cases levels rose threateningly within a few hours of dialysis.

Immediately after admission to our surgical unit, all 59 patients were rehydrated and electrolyte normality was re-established (with forced diuresis, when necessary) using frusemide Mithramycin was given to five patients. Forty-four patients (75 per cent) underwent surgery within 48 h of admission, 12 patients (20 per cent) between day 2 and day 8, and three patients (5 per cent) on day 10. Surgery was delayed for the latter 15 patients to allow treatment for concomitant diseases (diabetes, heart and respiratory failure), and in five cases to investigate the hypercalcaemia. Rapid volume replacement was instituted if hypovolaemic shock was predominant, followed by infusion of isotonic or hypotonic solution according to the type of dehydration. Infusion volumes were sometimes very high and involved careful monitoring of the central venous pressure. Most of the patients required only rehydration, which produced a fall in serum calcium levels to below 3 22 mmol/l (130 mg/l) in 14 patients Forty-five patients had forced diuresis with 40–100 mg frusemide intravenously. This treatment was started after dehydration had been treated and slight volume expansion achieved. Losses, which may be considerable (1–2 litres per hour of sodium-rich and potassium-rich urine), were assessed by means of hourly urine volume and electrolyte measurement Frusemide infusions were repeated whenever the hourly urine volume was <500 ml. Infusion fluids consisted of isotonic glucose with the addition of small amounts of sodium

Table 1 *Frequency of severe clinical signs in 59 patients with acute primary hyperparathyroidism*

Clinical sign	%
Severe weakness	88
Altered states of consciousness	65
Severe dehydration	65
Rapid weight loss	60
Vomiting	30
Coma	7
Acute pancreatitis	4

chloride and potassium, equal to urinary losses. Magnesium sulphate was given orally. All patients who underwent surgery were fully hydrated and in optimal electrolytic and physical condition. Only ten patients had serum calcium levels within normal limits or hypocalcaemia at the time of surgery (day 0); 38 patients had serum calcium levels above 3·22 mmol/l, and 15 patients maintained a level ≥3·75 mmol/l (*Figure 1*).

Surgery

Surgery was performed under general anaesthesia by experienced parathyroid surgeons. Two patients had already undergone an unsuccessful neck operation in another hospital. Cervical exploration was performed in all patients regardless of the results of parathyroid localization investigations. When the pathological parathyroid lesion was located, the other glands were routinely sought. Parathyroid lesions were found during cervical exploration in 57 patients. The lesion was located in the lower mediastinum in the other two patients and sternotomy was necessary, the first case immediately after the neck exploration and the second case 7 days later.

The parathyroid lesions were as follows: parathyroid adenoma (55 cases), primary hyperplasia of four parathyroid glands (two cases) and parathyroid cancer (two cases). Severe hypercalcaemia was caused mainly by large lesions (2–5 g), although much smaller lesions were found. Histology revealed recent haemorrhagic necrosis and cystic areas in 60 per cent of adenomas. Overall, results were striking: serum calcium levels returned to normal within 24–48 h and, above all, there was almost immediate recovery of consciousness and disappearance of any existing abdominal and bone pain.

None of the patients died before surgery. Three patients had recurrent nerve paralysis; in one of these cases, the nerve was cut intentionally during the excision of a parathyroid cancer. During the postsurgery period, three patients had very low serum magnesium levels, induced by forced uncompensated diuresis and revealed by gradually increasing mental confusion, which regressed rapidly following administration of magnesium phosphate. After surgery, 21 patients were hypocalcaemic with distal tingling, but there were no cases of severe tetany Myocardial ischaemia occurred in two patients and pulmonary infection in one. One patient died of pulmonary infection 2 months after surgery.

Discussion

Acute hyperparathyroidism is rare. Its incidence in primary hyperparathyroidism varies from 5 to 10 per cent depending on the study[1–3]. Its incidence is increasing, not because of an increased prevalence of acute hyperparathyroidism but because calcium measurement in hospital patients is now routine[4].

The clinical signs of acute hyperparathyroidism in this study were similar to those previously reported[3]. In most cases, the acute episode revealed the underlying disease. However, it is important to note that a third of our patients had had typical, but neglected, signs of hyperparathyroidism for several months and even years before diagnosis[5]. There was not a predictable correlation between the high level of serum calcium and clinical severity, particularly in relation to disordered consciousness[6]. One of the patients was followed up after he refused surgery. His calcium was >4 mmol/l (160 mg/l) but he had no neurological disorder. In our study involving 1000 cases of primary hyperparathyroidism, several patients showed no serious symptoms in spite of calcium levels >3·75 mmol/l (150 mg/l).

In most cases, 1 or 2 days should be enough to assess severe hypercalcaemia and make an accurate diagnosis[3,4,6–9]. Such investigation generally helps to identify other causes of high serum calcium. The diagnosis of acute hyperparathyroidism was rejected 13 times in this series. In doubtful cases suppression of the hypercalcaemia after administration of steroid will exclude sarcoidosis and malignancy. Vitamin D intoxication is usually reported during questions on past history. However, this went unnoticed in one patient who underwent an emergency operation.

In doubtful cases, surgery must be carried out even when the cause of the hypercalcaemia is in doubt; one of our patients had myeloma[8] and another had retroperitoneal leiomyosarcoma, and both were associated with acute primary hyperparathyroidism. We believe it is preferable to carry out a negative cervical exploration than to leave in place an adenoma inducing acute hyperparathyroidism. No mortality was reported in the nine patients who underwent surgery after erroneous diagnosis.

Only surgery can provide proper treatment of acute hyperparathyroidism. Medical treatment before surgery is intended to provide rehydration, to correct electrolyte disorders, and to lower serum calcium to less dangerous levels. However, it is not necessary to obtain normal levels, and surgery must be carried out as soon as the patient's clinical condition and metabolism improve sufficiently. Even if there is no clinical improvement, particularly with regard to consciousness, after several hours of medical treatment, patients should rapidly undergo surgery[6,7]. We consider that this policy accounts for the low mortality rate in this series, whereas the mortality rate exceeds 30 per cent when medical treatment is extended[4,9,10]. Cervical exploration must be performed by experienced surgeons Although in the majority of cases the adenomas are voluminous, exposure of all four glands is essential, especially when the lesion seems small in proportion to the serum calcium level. Two of our patients had primary hyperplasia. If cervical investigation fails to find a parathyroid lesion, sternotomy must be performed immediately when there is acute hypercalcaemia; this is in contrast to our usual procedure for hyperparathyroidism.

We conclude that acute hyperparathyroidism can be reliably and confidently treated if prompt resuscitation is followed by urgent surgery.

The development and evaluation of a clinical test of surgical resident proficiency

Benjamin O. Anderson, MD, John H. Sun, MD, Ernest E. Moore, MD,
Laetitia L. Thompson, PhD, Alden H. Harkin, MD, *and* **Edward J. Bartle, MD,**
Denver, Colo.

The two purposes of this study were to develop a clinical test of surgical resident proficiency and to compare this clinical test with currently applied methods of resident evaluation. Appendicitis is a common surgical disease, and its accurate diagnosis depends largely on clinical acumen. Ten third-year surgical residents prospectively evaluated 107 patients admitted because of suspected appendicitis. After taking a history, performing a physical examination, and reviewing laboratory data, these residents were asked to state, as a percentage, the likelihood that each patient had appendicitis. Sixty-three patients had appendicitis documented by pathologic inspection after appendectomy. Forty-four patients did not have appendicitis, as was determined by operation (17) or by in-house observation and resolution of abdominal pain (27). These outcomes were used to calculate a diagnostic ability score (DAS) for each resident. Residents were evaluated by standard methods including in-service examinations and monthly evaluations by the attending staff. Residents were also evaluated by nonstandard, but potentially useful, neuropsychologic and psychologic tests, including the trail making test, the Ravens progressive matrices test, the paced auditory serial addition test (PASAT), the grooved pegboard test of manual dexterity, and the profile of mood states (POMS) psychologic questionnaire. Cumulative scores were calculated and compared by multiple regression with coefficient variance analysis. The correlation (R^2) of DAS with standard evaluation techniques was as follows: In-service (0.055), faculty (0.508), trails (−0.293), Ravens (0.028), PASAT (0.251), dexterity (0.432), POMS (0.381). We found that (1) the DAS is a discriminating clinical test; (2) the DAS correlates with subjective faculty evaluation; and (3) the DAS does not correlate with in-service examination scores. We conclude that faculty evaluation remains the best currently applied test of surgical resident clinical proficiency as measured by the DAS. (SURGERY 1989;106:347-53.)

From the Departments of Surgery and Psychiatry, University of Colorado Health Sciences Center, Denver, Colo.

THE GOAL OF resident testing is to monitor the acquisition of medical knowledge and development of clinical proficiency during training. Most surgical residency programs use the American Board of Surgery in-service training examination to follow resident progress, but the validity of this test to assess clinical proficiency in surgery has been questioned.[1] Although the in-service examination has been found to correlate with the written section of the American Board of Surgery qualifying examination,[2] it has not been demonstrated to correlate with clinical performance. The two purposes of this study were to develop a simple clinical test to assess resident proficiency and to correlate this test with currently applied methods of resident evaluation, including the in-service examination, monthly faculty evaluation, and neuropsychologic and psychologic tests.

METHODS

Resident group. Admitting surgical residents at Denver General Hospital and the University of Colorado Hospital were asked to participate in this study from February 1986 to December 1987. In the normal course of their duties, these third-year residents evalu-

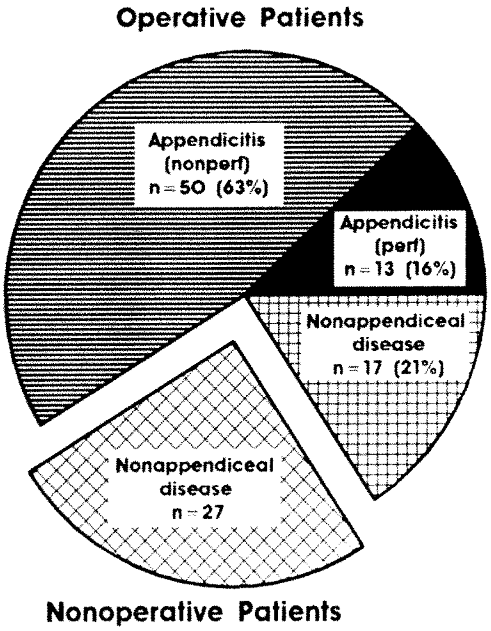

Fig. 1. Distribution of patients by operative status and final diagnosis. Operative patients were diagnosed with appendicitis or nonappendiceal disease on the basis of their pathologic reports. Nonoperative patients had complete symptomatic resolution and were assumed to have nonappendiceal disease.

Fig. 2. Distribution of diagnostic ability scores among 10 surgical residents. The DAS is a discriminating clinical test based on the diagnosis of appendicitis.

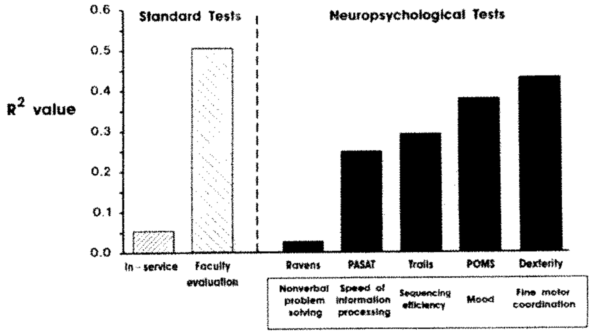

Fig. 3. Correlations between DAS and currently applied measures of resident ability. The strength of linear association between the DAS and other tests was measured by R^2 values, calculated from the Pearson correlation coefficient *(R)*. The DAS correlated most strongly with faculty evaluation and intermediately with neuropsychologic tests. The DAS did not correlate with the in-service examination.

vidual scores were independently correlated with the DAS, and the best R^2 value of the group was reported. Lastly, R^2 values less than 0.30 were interpreted to indicate that there was no correlation between the two variables being compared.

RESULTS

Fourteen surgical residents evaluated 115 patients for possible appendicitis. These residents had similar degrees of experience with appendicitis, each having seen a minimum of 20 cases before initiation of the study. Four residents who entered three or fewer patients were eliminated from analysis because their data pools were thought to be too small to be meaningful. The 10 remaining residents evaluated 107 patients, forming the data base for this study (Fig. 1). Of these 107, 63 patients (59% of the total population) were found to have appendicitis at laparotomy (50 nonperforated, 13 perforated). Seventeen patients were found to have nonappendiceal disease at operation (16 laparotomies, one laparoscopy). Three of the 16 laparotomy patients with nonappendiceal disease had other problems warranting surgical attention (perforated Meckel's diverticulum, perforated cecal ulcer, bowel obstruction from adhesions). For DAS calculation, the Meckel's diverticulum and cecal ulcer patients were counted as appendicitis patients to avoid penalizing residents for essentially correct diagnoses. The remaining 13 operative patients had nontherapeutic laparotomies (16% of the operative group). Ten of the 13 were women in the child-bearing years. The 27 nonoperative patients were observed and discharged after resolution of their symptoms. None returned with further complaints of abdominal pain.

Diagnostic ability scores were calculated for each resident and ranged from 62.4 to 88.6, with a mean of 74.0 and a standard deviation of 7.8 (Fig. 2). The DAS was correlated with other tests by linear regression and the calculated R^2 values were compared (Fig. 3). Faculty evaluations correlated best with the DAS ($R^2 = 0.508$), and in-service examination scores did not correlate with the DAS (Fig. 4). Less than 6% of the variation in in-service scores among residents could be attributed to a linear relationship between those scores and the DAS. Among the neuropsychologic and psychologic tests, the scores correlating best with the DAS were the dominant hand score of the grooved pegboard dexterity test ($R^2 = 0.432$) and the confusion score of the POMS psychologic questionnaire ($R^2 = 0.381$).

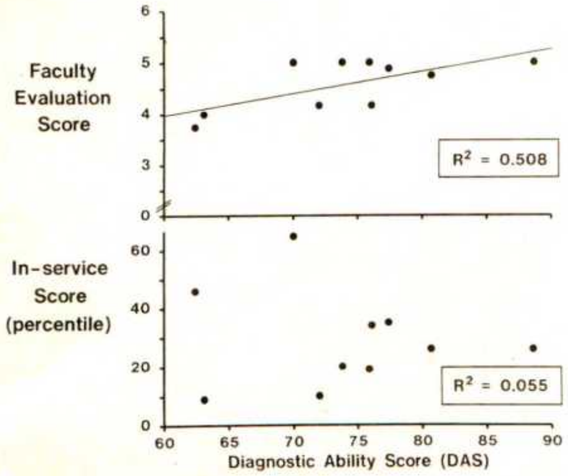

Fig. 4. Relationships between DAS and faculty evaluation (above) and in-service examination (below). Resident scores are represented by points with DAS on the x-axis and faculty evaluation/in-service examination scores on the y-axes. DAS correlated with faculty evaluation and did not correlate with in-service examination scores.

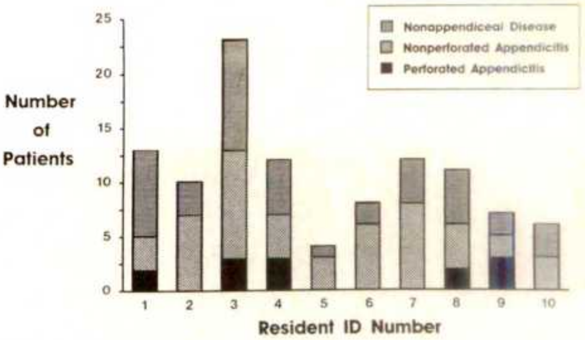

Fig. 5. Characteristics of patient subgroups evaluated by different residents. Patient subgroups varied in the total number of patients, the percentage of patients with appendicitis, and the percentage of appendicitis patients with perforation. Subgroups also varied in the percentage of female patients (not illustrated here).

The remaining neuropsychologic tests did not correlate with the DAS. No written test correlated with the DAS as strongly as faculty evaluation.

Because each resident evaluated a different subgroup of patients, characteristics of the patient subgroups were correlated with the DAS to determine whether scores were biased by patient sampling. As illustrated in Fig. 5, patient subgroups varied in the total number of patients (ranging from 4 to 23), the percentage of female patients (ranging from 25% to 73%), the percentage of patients demonstrated to have appendicitis (ranging from 38% to 78%), and the percentage of appendicitis patients demonstrated to have perforation (ranging from none to 60%). Each of these characteristics was correlated with the DAS, and R^2 values were calculated (Fig. 6). The total number of patients, the percentage of female patients, and the percentage of appendicitis patients with perforation did not correlate with the DAS ($R^2 = 0.269$, 0.051, and 0.075, respectively). The percentage of patients with appendicitis (perforated and nonperforated combined) did correlate with the DAS (Fig. 7), but the degree of correlation was marginal ($R^2 = 0.311$). No characteristic that varied among patient subgroups correlated with the DAS as strongly as did faculty evaluations ($R^2 = 0.508$).

The degree of correlation between faculty evaluation and the DAS was enhanced in the subset of residents who evaluated the most patients. For the entire group of 10 residents, the degree of correlation ($R^2 = 0.508$) was significant by the t test at the $p < 0.05$ level ($t = 2.87$). For the six residents who evaluated 10 or more patients, the degree of correlation was increased ($R^2 = 0.808$), which is significant at the $p < 0.02$ level ($t = 4.10$). For these six residents there was still no correlation between in-service scores and the DAS ($R^2 = 0.001$), and the degrees of correlation between neuropsychologic test scores and the DAS were relatively unchanged.

COMMENTS

Appendicitis is a common surgical problem, and its diagnosis depends largely on clinical acumen. Despite technologic developments, no major improvement in the preoperative diagnosis of appendicitis has been made in the past 30 years.[5] Individual diagnostic studies, such as barium enema and ultrasonography, and laboratory tests, such as white blood cell count with differential, have been scrutinized for their ability to distinguish appendicitis from nonappendiceal disease.[6-8] Other authors have devised scoring systems based on history and laboratory findings to aid in the diagnosis of appendicitis.[9, 10] Most experts agree, however, that no single finding defines the diagnosis of appendicitis,[11, 12] and advanced diagnostic tools are, at best, an adjunct to the clinician's subjective decision-making process, which is based largely on personal experience and ability to integrate data.[13] The diagnosis of appendicitis, then, is a reasonable clinical problem for the assessment of clinical profiency among residents at similar levels of training.

A test of clinical proficiency (DAS) was created for this study on the basis of residents' confidence and

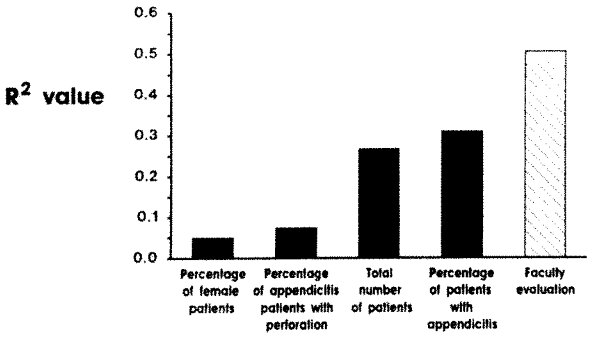

Fig. 6. Correlations between DAS and characteristics that varied among patient subgroups evaluated by different residents. No patient subgroup characteristic correlated with DAS as strongly as did faculty evaluation.

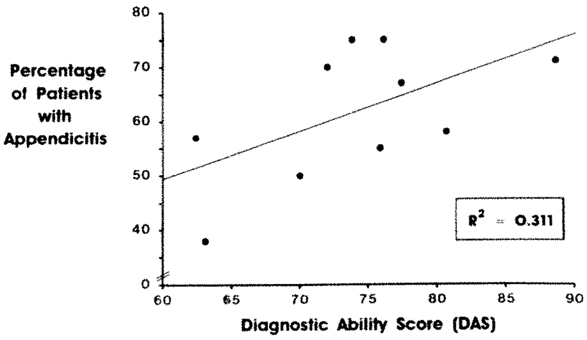

Fig. 7. Relationship between DAS and percentage of patients demonstrated to have appendicitis (perforated and nonperforated appendicitis combined). Residents who evaluated a greater percentage of patients with appendicitis tended to score more highly on the DAS.

accuracy in the diagnosis of appendicitis as verified by clinical outcome. This outcome was determined by the pathologist to be appendicitis or nonappendiceal disease for operative patients, but was assumed to be nonappendiceal disease for nonoperative, spontaneously recovered patients. This assumption may not be true in every case. Occasional pathologic reports describe cellular changes consistent with resolving appendiceal inflammation,[12] indicating that acute appendicitis does not invariably progress to perforation. Such changes were noted in one of the 87 pathologic reports reviewed for this study. The existences of recurrent and chronic appendicitis also suggest that appendicitis can spontaneously resolve. These entities, however, have incidences of, at most, 10% and 1.5%, respectively.[14] The spontaneous resolution of acute appendicitis appears to be an uncommon event and probably does not significantly affect the accuracy of the DAS.

The DAS was found to be a discriminating clinical test. Residents reported varying degrees of certainty in their diagnoses of appendicitis and nonappendiceal disease that, when averaged, resulted in a spectrum of DAS scores. Factors potentially contributing to this variation in scores other than diagnostic ability were controlled within practical constraints. Extensive prior experience with the diagnosis of appendicitis presumably improves a resident's diagnostic confidence and accuracy. As a result, residents at the same level of clinical training were selected for analysis. Differences among patient subgroups seen by different residents could also alter overall scores because some patients' conditions may be more easily diagnosed than others. For this reason, residents who entered fewer than four patients into the study were eliminated from analysis. Characteristics that varied among the remaining patient subgroups were then correlated with the DAS to determine if an overt differences among subgroups biased the resulting scores. Only the percentage of patients with appendicitis correlated with the DAS, and the degree of this correlation was marginal ($R^2 = 0.311$). This indicates that appendicitis may be, on the whole, easier to confidently diagnose than nonappendiceal disease. This result might have been anticipated because appendicitis patients tend to exhibit more obvious signs and symptoms as their disease progresses toward perforation. It would appear that the variation in DAS scores among residents reflects a true difference in diagnostic confidence and accuracy for appendicitis and is, at most, marginally affected by other factors.

The commonly accepted premise that diagnostic accuracy improves as more patients are seen could not be verified in this study. The number of patients in subgroups evaluated by different residents failed to correlate with the DAS, indicating that residents who evaluated more patients did not necessarily have higher DAS scores. (It would be interesting to repeat this study using the same residents in later years of training to determine if the DAS improves in subsequent stages of clinical development.) Despite its lack of correlation with the DAS, the number of patients evaluated by individual residents remains an important consideration. The validity of the DAS as a measure of diagnostic ability hinges on each resident's evaluating a sufficient number of patients to adequately sample his or her clinical skill. A minimum of four patients was arbitrarily selected for DAS calculation, but a higher minimum would presumably increase the validity of the scores. For this reason, statistical analyses were repeated using the subset of six residents who evaluated 10 or more patients, and it was verified that the observed correlations for the entire group of 10 residents persisted for the more select group.

SUMMARY

The DAS was developed as a clinical test of resident proficiency and was compared with currently applied methods of resident evaluation. The DAS correlated with faculty evaluations but did not correlate with in-service examination scores. Neuropsychologic and psychologic test scores either did not correlate with the DAS or correlated less strongly with the DAS than did faculty evaluation. When the same statistical analyses were performed using the test scores of the six residents who evaluated 10 or more patients, the same findings were observed. Furthermore, the level of significance of correlation between faculty evaluation and the DAS was enhanced from $p < 0.05$ to $p < 0.02$. We conclude that subjective faculty evaluation remains the best currently applied test of surgical resident clinical proficiency as measured by the DAS.

Anergy in patients with biliary lithiasis

Sir

I was intrigued to read the report regarding 'Anergy in patients with biliary lithiasis' (Cainzos *et al. Br J Surg* 1989, **76**. 169–72) However I feel that their conclusions, that patients with acute gallstone cholecystitis demonstrate evidence of impaired host immunity, are overstated

At this stage it is well recognized that jaundiced (icteric choledocholithiasis in this series) patients are immunosuppressed. This is based on several studies which have examined a number of parameters of immune function in the presence of hyperbilirubinaemia[1,2]. The type of immune dysfunction would appear to depend upon the underlying disease process[3] Patients with obstructive jaundice exhibit impaired lymphocyte responsiveness probably owing at least in part to the suppressive action of the bile salts[4]. This deficiency is also likely to be contributed to by the presence of underlying malignancy in a proportion of cases It is clear from my own studies that the generation of interleukin 2 is also markedly reduced in the presence of jaundice (unpublished data).

However, the evidence with respect to the patients with cholecystitis is rather more sketchy It is generally appreciated that patients with an active inflammatory process such as infection will exhibit impaired cell mediated immunity. I believe that to suggest that the patients with acute cholecystitis represent anything more than simple infected/inflamed cases cannot be sustained Furthermore, there is no reason to think that patients with gallstones are immunosuppressed – because that is the obvious extrapolation of these data

I believe that this paper provides significant contributory data to the field of jaundice and immunity derived from the patients with common duct stones. Beyond that, I believe that the comments related to the patients with acute cholecystitis are not relevant to the area of biliary disease Rather, they represent an example of the totally separate issue of immunity and acute inflammation.

Authors' reply

Sir

I have read with interest the comments which Dr Monson has made on my paper and I am very grateful because he tries to contribute to the clarification of the complex relationship which exists between hyperbilirubinaemia and the abscence of impaired cell mediated immunity.

However, I think that his letter needs some clarification·

1 In our study, we have not tried to establish which is the ultimate cause that permits us to know why the patients with jaundice present an alteration of cellular immunity. We have simply pointed out a clinical phenomenon which we had already previously described in jaundiced patients with diverse aetiology[1]; but now we want to make it more concrete and detailed by limiting it exclusively to patients with a biliary lithiasis. We obviously know the articles, and their results, that Dr Monson speaks of, but we obviously have no knowledge of his own results because they have still not been published

2. It is obvious to any Doctor that, by definition, acute cholecystitis is an inflammatory and infectious process and that, because of this, delayed cellular immunity can be disturbed However, *Table 4* of our article demonstrated that the cause of this alteration is not due to the infectious or inflammatory process

3 We are surprised that Dr Monson has arrived at the conclusion that the obvious extrapolation of our paper is that the patients with biliary lithiasis are immunosuppressed

The only conclusion that can be drawn is that the patients with choledocholithiasis and jaundice, and those who presented acute cholecystitis, present an alteration of delayed cellular immunity. The other clear conclusion of our study is that patients with simple cholelithiasis have as low a probability of presenting anergy or relative anergy as a control group of absolutely healthy subjects

Necrotizing pancreatitis

Sir

McMahon's group have contributed a timely, scientific and practical guide to the treatment of necrotizing pancreatitis (*Br J Surg* 1989, **76**: 465–71). A similar approach has been advocated recently by Howard[1]. We have treated seven patients with a similar initial strategy of non-operative management, delaying surgical debridement until demarcation occurs or until a potentially life-threatening complication develops. The latter was usually indicated by increasing leucocytosis with a decline in renal or hepatic function, i.e the first sign of impending systemic sepsis or multiorgan failure Using a Chevron incision, a mesocolic approach to the pancreatic necrosis, and radical debridement with hemicolectomy if indicated for extension of necrosis to retrocolic fat, reintervention is minimized. In three of our patients only one surgical procedure was required, although drainage of necrotic material continued for up to 60 days. In the other four patients, multiple (mean 3·8) interventions were necessary; this reoperation rate could probably be reduced with the use of an irrigating silicone elastomer drain as described by the Leeds group. Ventilatory support (four patients), haemodialysis (two patients) and prolonged treatment in an intensive care unit were required by our patients, and one patient eventually died from continuing sepsis Only one patient required insulin on recovery, indicating that the necrotic tissue was largely dead adipose tissue Pancreatography some months later often demonstrates a pancreatic duct of relatively normal length and configuration[2].

Two important issues are raised by the success of the Leeds group First, the value of prognostic scoring and preoperative scoring The decision to operate was based on the evolution of contrast-enhanced CT or clinical deterioration; the scoring system appears to have played no role. It is doubtful whether the scoring systems are even of value for comparison of results from different centres because they are indicative of a sick patient rather than a sick pancreas. Only histology can make a diagnosis of necrosis and its anatomical extent Second, the life-threatening events occurring in the progression from pancreatic oedema to necrosis appear to take place in the peripancreatic fat. As yet, the involvement of cytokines, interleukins or similar agents with potent inflammatory activities on the lethal upheavals occurring in this juxtapancreas adipose tissue have not been explored

Double lumen and quadruple lumen pouches

Sir

Following our recently published prospective randomized trial of double lumen (J) and quadruple lumen pouches (W) (*Br J Surg* 1988, **75** 1008–11), we would like to present the functional results at 12 months following ileostomy closure on the 30 patients detailed in *Table 3* of the original article The data are expressed as the median and approximate 95 per cent confidence intervals[1] Continuous variables in two independent groups were analysed using the Wilcoxon two-sample test. Proportions were compared using a Fisher's exact test Significance was assumed if $P<0·05$ on a two-tailed test

Daytime frequency of defaecation was not significantly different between the 15 J pouch patients. 5(4–6) compared with the 15 W pouch patients. 4(3–6), $P=0·34$ However, night-time defaecation frequency was significantly less in the patients with a W pouch· 1(0–1), compared with the J pouch patients: 1(1–2), $P=0·03$ This was not entirely due to an increased number of patients having to rise at night to defaecate with a J pouch (13/15) compared with those with a W pouch (9/15), $P=0·215$. The number of patients that experienced episodes of fluid soiling per anus of sufficient quantity to necessitate the wearing of a pad was similar in both groups by day J(1/15) *versus* W(2/15); $P=0·96$ and by night· J(4/15) *versus* W(6/15), $P=0·7$.

There were no episodes of incontinence to faeces in any of the 30 patients One patient in each group was unable to defer defaecation for more than 10 min Both of these patients had evidence of active acute pouch inflammation (pouchitis) on sigmoidoscopic and histological criteria The number of patients taking antidiarrhoeal medication was identical in each group (7/15), as was the number of patients able to discriminate flatus from faeces (12/15).

The similarity of overall functional result was illustrated by a functional score (*Table 1*) for J pouch patients of 2(2–4), compared with a score for W pouch patients of 2(0–4); $P=0·77$.

Table 1

	Functional aspect	Score
1	24-h frequency of defaecation >6	1
2.	24-h frequency of defaecation >10	1
3.	Night-time defaecation	1
4	Defer defaecation <10 minutes	1
5.	Nocturnal fluid leakage per anus	1
6	Daytime fluid leakage per anus	1
7	Wearing of pads	1
8	Taking antidiarrhoeal medication	1
9	Incontinence to faeces	1
10	Absence of discrimination between flatus and faeces	1

This brief functional update of 30 patients who had previously been randomized to either J or W pouches has revealed a similar clinical outcome at 12 months to that reported at 4 months following restoration of intestinal continuity The lower nocturnal defaecation frequency in the patients with a W pouch has been described by others[2]; however, we did not subsequently show a difference in the proportion of patients taking antidiarrhoeal medication

Despite an identical method of ileo-anal anastomosis in each group, a greater number of patients with a W pouch experienced both daytime and night-time soiling episodes compared with J pouch patients, although the difference did not achieve statistical significance.

We see no reason, therefore, to alter the conclusion stated following the initial report of the trial.

Stapled ileal J pouch–anal anastomosis

Sir

We are concerned by the message conveyed by Brough and Schofield (*Br J Surg* 1989, **76**: 350–1) regarding the need to evert the rectum to facilitate placement of a distal purse-string suture during the performance of a stapled ileal J pouch–anal anastomosis We believe the technique to be at best unnecessary and at worst exposing the patient to avoidable postoperative sphincter damage Alternative techniques have been described which enable the rectal stump to be cross-stapled[1], so avoiding the use of a purse-string suture completely Indeed, an article in the same edition of *The British Journal of Surgery*[2] details some of the problems associated with purse-string sutures while describing a technique that avoids the use of both an ileal reservoir purse-string suture as well as one around the rectal stump

Ileal reservoir anastomosis at the dentate line has been shown to be associated with inferior functional results compared with anastomosis at the top of the anal canal[3]. The risk of malignant change in the remaining 1 cm of mucosa is small[4] and the grade of inflammation low[5] Clearly this small risk cannot be ignored, however, inspection of the remaining mucosa is facilitated by the use of a long proctoscope or a paediatric sigmoidoscope We do not share the authors' optimism that 'eversion of the rectal stump does not alter anal function' Data are lacking, but Goligher[6] questioned the validity of comparisons made by himself and others using unmatched patient groups with small numbers and multiple uncontrolled variable factors

Martin[7] described a nocturnal soiling rate of less than 5 per cent in 105 patients (age range 8–69 years), all of whom had a mucosal proctectomy performed from the abdominal route The anastomosis was at 1 cm above the dentate line with the ileal reservoir being hand-sutured and the anastomosis performed endoanally.

Although an increased length of follow-up could have accounted for some of the functional improvement, his results are better than those reported from a recent review of the results of nine separate centres[8].

A recent report of a series of 100 patients, all of whom had a rectal eversion technique performed as part of their ileal reservoir procedure[9], ended with the author describing a nocturnal soiling rate of 25 per cent 12 months following ileostomy closure

Details of the incidence of postoperative bladder and sexual disturbances are lacking as are details of manometry technique We would also question whether retention of semisolid porridge reflects the preservation of continence in the early postoperative stage when stool consistency is liquid and the majority of soiling episodes documented have occurred at night[8]

With the recent emphasis on minimal stretching of the anal sphincter[2,3] during ileal reservoir anastomosis to the anal canal, we feel that eversion of the rectal stump exposes patients to the risk of avoidable complications not only due to excessive sphincter stretch but also to a traction neuropathy of the multiple delicate perirectal autonomic nerves

Book reviews

A Colour Atlas of Extra-anatomic Bypass for Lower Limb Vascular Disease

J. Chamberlain. 265 × 195 mm Pp. 64. Illustrated 1988 London Wolfe Medical Publications Ltd. £19.00.

This volume contains 92 colour illustrations, the vast majority consisting of photographs of various stages of operations to insert axillofemoral and femorofemoral grafts. No extra-anatomical bypass to the legs other than these two procedures is mentioned and while some may be disappointed by the incomplete coverage of the title topic, others will appreciate the concentrated effort made to describe what are, after all, by far the commonest two extra-anatomical operations

The indications and aftercare relevant to the surgery are briefly covered and most space is given to the techniques of graft insertion. Perhaps because this is essentially a 'how I do it' manual, it can appear dogmatic at times, with little attempt to discuss alternatives or grey areas. For instance, only standard Dacron® is used as a graft, without mention of polytetrafluoroethylene, sealed Dacron or externally supported prostheses as possible alternatives. Similarly, routine drainage of vascular surgical wounds is advocated without any indication that this may not be a widespread practice. These are only two of many examples which are all the more significant in a book without references or bibliography Nevertheless, it cannot be denied that the omission of discussion of controversial points allows a clear and concise exposition which some may find attractive.

The most useful role for this book may be as an aid for the surgeon in training who might find its illustrations and commentary helpful when used in conjunction with a more extensive and referenced textbook of vascular surgery.

Advances in Urology

B. Lytton, W. J. Catalona, L. Lipshultz, E. McGuire. 230 × 160 mm. Pp. 318. Illustrated. 1988. Chicago: Year Book Medical Publishers Incorporated. £35.50.

This is Volume 1 in what I presume will be a series from Yearbook Medical Publishers Incorporated

It consists of a dozen chapters in which authors almost exclusively from the USA give a broad view of their field. A wide variety of subjects are covered with a comprehensive list of recent references at the end of each chapter. The book starts with a chapter from Robert Weiss of Yale on the very difficult subject of the dilated upper urinary tract and is followed by a useful chapter on ultrasound which is likely to become more and more important to the practising urologist once the problem of the interface with the radiologist has been solved. Certainly I believe that urologists in the future will have to be skilled in this extremely useful technique. The place of CT scanning in renal trauma and the more controversial management of carcinoma *in situ* of the bladder with photoradiation therapy are reviewed. Technical chapters include endoscopic treatment of upper urinary tract tumours, microvascular vasectomy reversal and continent urinary diversion with its proliferation of cystoplasties and pouches. Two helpful chapters on the present place of chemotherapy in testicular tumours and another two on the therapy of impotence, including a detailed list of currently available prostheses, are included A short chapter on *in vitro* fertilization as therapy for male infertility seemed an odd choice but the authors claim this was a useful adjuvant to conventional therapy. One major chapter was on extracorporeal shock wave lithotripsy with a brief historical view, clinical results and an appendix in which the second generation lithotripters and their characteristics are mentioned

This is altogether a very useful book for the practising urologist. Every urological department should have a copy and we look forward to future volumes

Gastroesophageal Reflux

G G. Jamieson and A. Duranceau, 152 × 229 mm. Pp. 281. Illustrated. 1988 Philadelphia. W. B. Saunders. £31.00

I was quite delighted to be asked to review this book as I was just about to buy it for myself and have therefore saved a few pounds It is a mine of useful information about the subject and is creditably up to date, which says something about the efficiency of the publishers. The authors have set out to provide a comprehensive account of relevant physiology, pathology, diagnosis and management. It is extremely well referenced and indexed and will no doubt be cribbed by lots of other writers for years to come. Casual readers will find it easy to dip into in small doses and the more serious will not find it too difficult to read from cover to cover

Far too many books on the oesophagus are thinly disguised symposium proceedings or just readjustments of the thoughts of well known contributors. This one is a welcome exception It should be added to every library and anyone who operates for reflux should actually buy a copy

An Atlas of Head and Neck Surgery

J. M. Loré. 190 × 267 mm. Pp 1200 Illustrated. 1988. Philadelphia W. B Saunders £85.00.

A generation ago some of us Europeans were privileged to be taught by the American princes of head and neck surgery The first edition of this book was our bible and *vade-mecum* and, indeed, for some of us it was our saviour! It was invaluable for its description of techniques which were not in common use in Europe at that time. It is symptomatic of the change that has come over this surgical subspecialty that this book has grown from 490 pages written by one man to 1200 written by fourteen

All the classical standard procedures are described for benign and malignant disease of the head and neck. However, one wonders if most of the material of the first five chapters (on radiographic anatomy, emergency procedures such as cardiac massage, basic techniques like needle biopsy, endoscopy and simple sinus surgery) have a place in this book. The management of epistaxis and the drainage of abscesses, too, could well have been omitted.

Sadly, much recent material has been omitted· for decompression of the orbit, the excellent exposure provided by an external ethmoidectomy approach is not mentioned, of the approaches to the nasopharynx, much the best, that is via a Le Fort I osteotomy, is not to be found It is surprising to see so much emphasis placed on the use of cervical flaps for reconstruction of the cervical oesophagus, and no mention of the use of revascularized jejunum. The techniques described were abandoned in most large European centres about 20 years ago.

The chapter on flaps contains a good account of the pectoralis major flap, but the rest of this chapter is largely of historical interest only, there being numerous pages on techniques such as the use of the deltopectoral flap, which passed into disuse 10 years ago. The latissimus dorsi flap is not described, and microvascular surgery is dismissed in a few words.

The section on branchial fistulae and branchial cysts is confused and confusing as it is written as if the two were part of the same disease, whereas they are of course entirely different The mythical tract of a branchial cyst is fully described

A section on chemotherapy sits uneasily in this book – as is often the case the views in this chapter are based more on pious hopes than reality. The author states, with respect to adjuvant chemotherapy, that 'Definitive proof of the value of this approach requires carefully controlled studies' Twenty-two controlled trials, covering more than 3500 patients, have now been published. The overall improvement in survival is 3 per cent at the expense of a death rate from toxicity of 7 per cent The author does not mention these facts

Some of the writing is difficult to follow. Of blindness, one author says, 'When it is iatrogenic, it becomes such a sequelae of any surgical procedure that the *axiom primum non nocere* is most pungent ' I wonder what he meant

This book is intended for general surgeons undertaking the occasional foray into the head and neck As such it will continue to be useful as a description of basic and well established excisional techniques Those working in the larger European centres devoted to head and neck surgery will have to turn elsewhere for guidance on many current techniques, particularly in reconstruction

The Year Book of Vascular Surgery

J. J Bergan and J S T Yao 152 × 241 mm Pp 299 Illustrated. 1988 Chicago. Year Book Medical Publishers Inc £34.00

A yearbook of a surgical specialty, bringing to busy clinicians all that has been considered to be new in publications in their field for the last year, is a delightfully simple concept, and clearly of enormous value However, it is hard to think of any book which is more difficult to compile. Not only must the surgical literature be sifted regularly throughout the year, and interesting papers brought to the attention of the editors, but the editors and their team must then decide how much credence to give these publications which are of enormously variable scientific value and academic reliability The next problem is how much of the paper to publish A bald abstract may give too little information to be of any real interest to the reader, and it is clearly not possible in such a volume to publish the whole paper The authors have achieved an admirable compromise to the dilemma with which they were faced. They present expanded abstracts of their selected papers, most of which are followed by an appropriate editorial comment. The comments are very tactful but reading between their lines, the editorial opinion of the message of the work comes through loud and clear. The selected papers cover a wide spectrum of topics in arterial, venous and lymphatic disease.

Clearly the editors must be concerned that they may have missed valuable publications from their list, but I do not think they have missed many, indeed none that I have noted and would have wished to have seen included Bergan, Yao and their large team of assistant editors must be congratulated on this excellent work which should be essential reading for every surgeon involved in the management of arterial and venous disease

The Original Bassini Operation for Inguinal Hernia

A Chinaglia. 200 × 275 mm Pp 114. Illustrated 1988 Padua, Italy Piccin Nuova Libreria £22 00.

Bassini is a name well known to European surgeons. Bassini described outcome measurements after operation first, invented an approach to the thyroid, performed acromiothoracic amputation of the upper limb first, resected a femoral aneurysm first, and devised an operation for inguinal hernia. In these offshore European islands, Bassini's operation for inguinal hernia is remembered but rarely performed correctly as Bassini described it Whereas Bassini himself had excellent results from his hernia operation, in England and Ireland nothing but baneful outcomes have followed our local corruptions of Bassini's scrupulous technique (and the concept that underpinned it) The late Professor Alcide Chinaglia was a pupil of Bassini's last Chief Assistant, Professor Penzo. The Bassini heritage is thus passed on to Chinaglia through the University of Padova This beautifully illustrated monograph is the fruit of this inheritance The book is a worthy contribution to the centenary of a great surgeon· Edoardo Bassini, we salute you!

Microcomputers in Medicine

P D Coleridge and J H Scurr. 165 × 241 mm. Pp 205 Illustrated 1988 Oxford Springer-Verlag £40 00

This book is a series of chapters based on the proceedings of the Fourth Micro-medical Computer Workshop held at the Middlesex Hospital in September 1986 The 11 chapters present the experiences of a number of workers who have developed microcomputers for their own professional uses in a clinical and research environment Two main themes predominate The first one is the use of microcomputers in the development of clinical audit systems, largely on surgical wards, and is partly a reflection of the continuing trend to improved surgical audit throughout the country A number of different systems are described and anybody wishing to venture into using microcomputers for improving data handling within their office would find the experiences and the opinions of the authors helpful in starting their own system The second theme of the book is the sections relating to the development of microcomputer systems to assist in providing clinical services and the development of laboratory research facilities, particularly in vascular laboratories and research projects related to postoperative fatigue and the clinical use of total parenteral nutrition These chapters describe the methodology used for setting up these particular services and again would be of assistance to the newcomer to the field The book might perhaps have been enhanced by a chapter assisting the newcomer to understand the wide choice of computer hardware and software that is available, with some guidelines on how to choose the most appropriate system for his particular use, and also some speculation into the future of computers in the Health Service as the inevitable trend towards resource management The use of computers within the Health Service and the integration of these microcomputer systems into the larger systems could be a crucial aspect of future clinical policy

A Colour Atlas of Parathyroid Exploration

A Gunn. 265 × 195 mm. Pp 64 Illustrated 1988 London Wolfe Medical Publications Ltd £19.00

This is a delightful addition to the collection of 'Single Surgical Procedures' produced by Wolfe under the general editorial supervision of Professor W Walker. It is a delight because it is eminently readable, written by an enthusiast (whose enthusiasm is transmitted), well illustrated and contains just enough dogma to be tolerable and therefore accepted fully!

Minor criticisms are levelled which could so easily have been avoided: *Figures 18* and *69* and their legends are identical and noticeably so in a book of only 64 pages and 82 illustrations *Figure 70* should have had its units changed to SI units – current surgical trainees might wonder how a patient could survive with a calcium value greater than 15!

Visits to several centres specializing in parathyroid and thyroid surgery demonstrate that inevitable variations in technique occur without obvious influence on successful outcome or cosmetic result Examples might be the need or otherwise to infiltrate the skin with adrenaline before incision, the gradual acceptance of the lack of need of drains or dressings, or the use of absorbable or non-absorbable ligature material I believe the author might allow discussion on these more minor technical matters Less debate would be entertained (and rightly so) on the clear and comprehensive account of the strategy of exploration in hyperparathyroidism (primary or secondary) Emphasis is placed through the text and acknowledgements of the team work involved, while stressing the essential involvement of the surgeon in preoperative and postoperative decisions Corresponding acknowledgement of the necessary interaction with other colleagues is made; for example, the endocrinologist with patients in hypercalcaemic crisis or the radiologist in localization studies before re-exploration.

For those wishing to specialize in endocrine surgery, this book is essential reading before going to theatre to learn from those whose practice includes patients with hyperparathyroidism

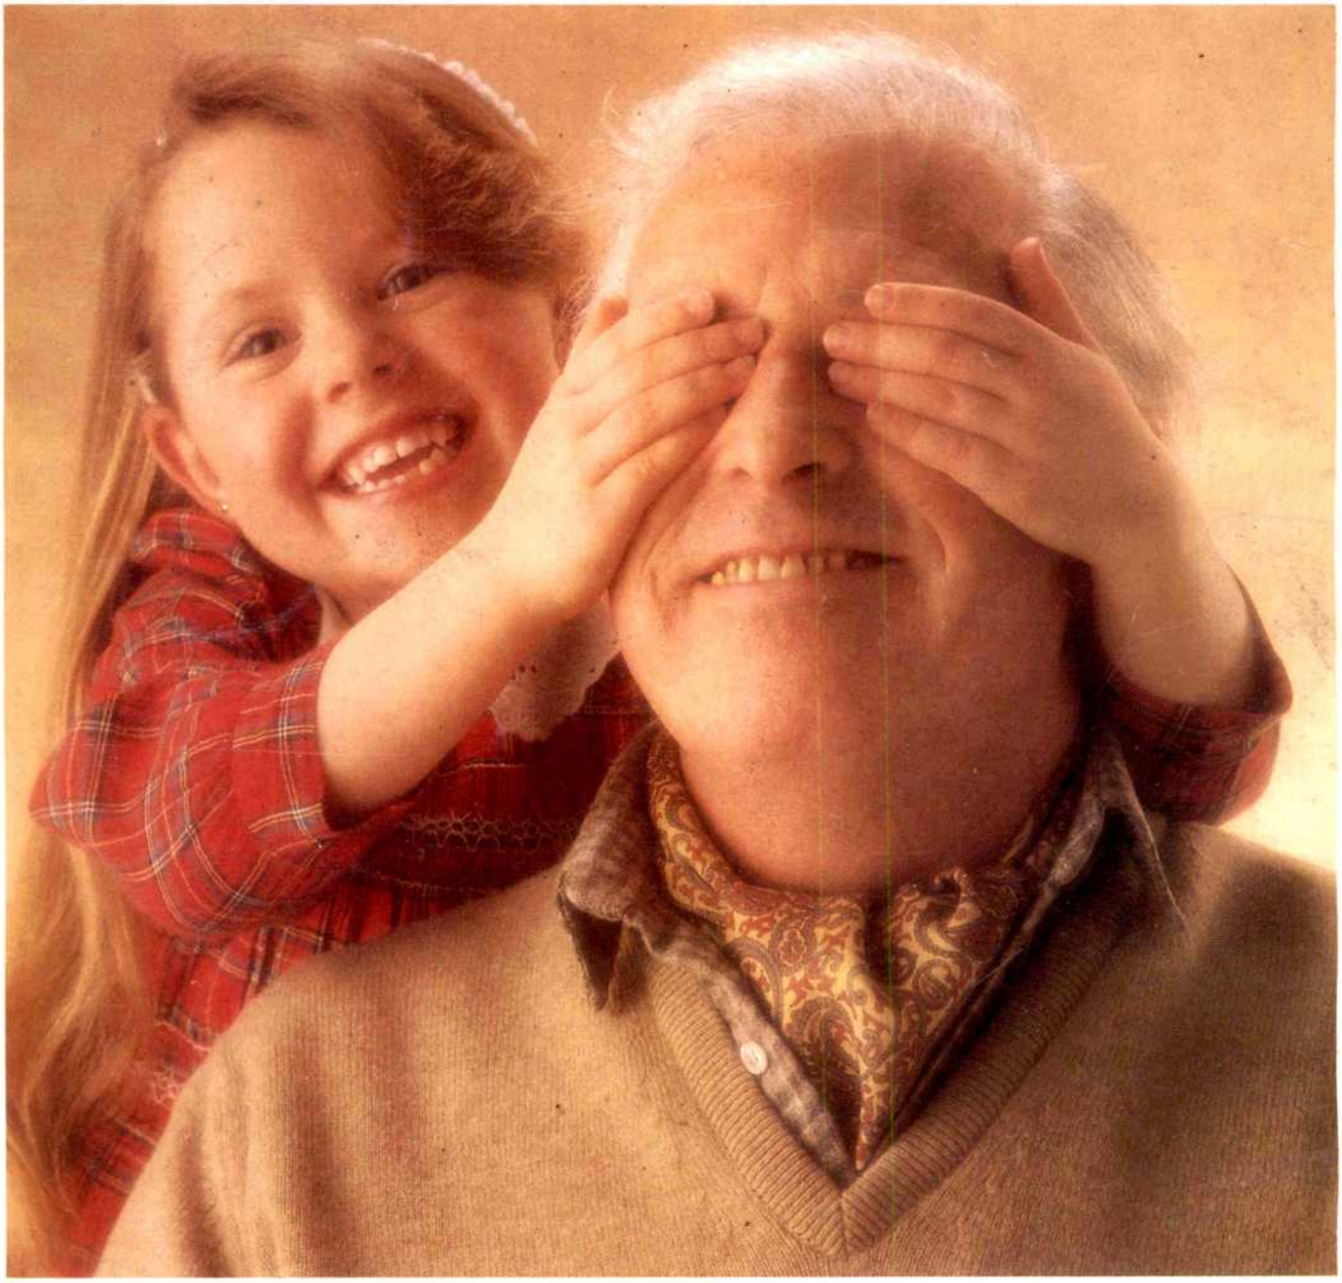
Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ 'ZOLADEX' PRESCRIBING NOTES.

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).
